AIEE Transactions Index for 1948

(Complete Index for Parts I and II of Volume 67)

1. Technical Subject Index

Accurate Time Control, Preliminary Consideration of Systems-Wide Load Divisions by Means of. Curtis, Pickslay....1562–9; disc. 1569
(Acoustics) An Electroacoustical System. Walker....35–40; disc. 40
Adjustable Brushes, A Study of the 3-Phase Commutator Armature With Six. Franklin....197–204
Aging Characteristics of Dry-Type Transformer Insulation at High Temperature. Stewart, Whitman....1600–06; disc. 1607
AIEE-ASME Standard Large 3,000-RPM Turbine Generators, Progress Report on. Mortensen, McClure, Lafloon....674–5; disc. 675
Air-Blast Circuit Breakers, Large Indoor Power. Jansson....1675–8; disc. 1679
Air-Blast 220-Kv 2,500-Megavolt-Ampere Reclosing Circuit Breaker, Performance Test of the Allgemeine Elektricitats Gesellschaft Free-Jet. Dovjikov, Diemond....295–304; disc. 304
Air-Borne Deposits, Insulators to Withstand. Taylor....1436–41; disc. 1441
Air-Break Switches, Service Restoration With Automatic. Reardon....64–71; disc. 71
Air Circuit Breaker, An Improved Design of Low-Voltage Panel-Mounted. Sperow, Fabre....695–8; disc. 698
Air Circuit Breaker for 23-Kv Arc Furnace Duty, A Compressed. Wilcox, Baker....154–8
Air Switch and a New Concept of Contact Performance, A New Outdoor. Killian....1382–7; disc. 1387
(Air Transportation) Proposed Circuit for Aircraft Reverse-Current Cutout. Marzolf....1246–8
(Air Transportation) Sensitive Relay Contact Protection Systems. Dallas, McCully....1204–07
Aircraft Control Element, A Polarized Relay as an. Johnson, Glassow....1249–55
Aircraft D-C Generators, Steady-State Analysis of. Van Valkenburg, Matthews....1351–8
Aircraft Generators, Analysis and Redesign of a Carbon Pile Voltage Regulator for. Kouwenhoven, Thaler....1197–1202; disc. 1202
Aircraft, Ground Power for. Blankenbuehler....1319–22; disc. 1322
Aircraft Reverse-Current Cutout, Proposed Circuit for. Marzolf....1246–8
Airplane, Starter-Generator Control System for a Multijet. Hart....1316–18
Airplanes, An Induction Generator Used With the All-Electric Automatic Pilot for. Vickers....182–5
Allgemeine Elektricitats Gesellschaft Free-Jet Air Blast 220-Kv 2,500-Megavolt-Ampere Reclosing Circuit Breaker, Performance Test of the. Dovjikov, Diemond....295–304; disc. 304
A-C Arc Behavior Near Current Zero by Means of Mathematical Models, A Study of. Browne....141–50; disc. 150
A-C Circuits, Arcing Fault Currents in Low-Voltage. Wagner, Fountain....166–72; disc. 172
A-C Electric Distribution Systems, Selective Tripping Arrangements for Protection of Ship's. Cole....1256–62; disc. 1262
A-C Resistance and Reactance of Large Conductors, Problems in the Measurement of. Salter....1390–6; disc. 1396
A-C Resistance of Large Size Conductors in Steel Pipe or Conduit. Wiseman....1745–52; disc. 1752
Aluminum Conductors, Joints and Clamps for. Tebo....1145–50; disc. 1150
Aluminum-to-Copper Connections, An Experimental Investigation of the Electrical Performance of Bolted. Bonwitt....1208–18; disc. 1218
Amalgam-Cathode Materials for Power Tubes. Lyon, Williams....627–30
America, Radio for Telephone Service in. Romnes....1060–7
Amplifier Stabilized for Zero and Gain, D-C. Williams, Tarpley, Clark....47–57
Amplifiers for Naval Shipboard Applications, Magnetic. Buechler....1241–5; disc. 1245
Analog Computer, A Large-Scale General-Purpose Electric. Harder, McCann....664–73
Analysis and Redesign of a Carbon Pile Voltage Regulator for Aircraft Generators, Kouwenhoven, Thaler....1197–1202; disc. 1202
Analysis of Aircraft D-C Generators, Steady-State. Van Valkenburg, Matthews....1351–8
Analysis of Control Systems, Graphical. Evans....547–51
Analysis of Unsymmetrical Machines. Burian....643–6
Analysis, The General Solution Method of Power Network. Dunstan....631–8; disc. 638
Analyzer, A Telegraph Signal. Erickson....380–4; disc. 384
Angle-Regulator Characteristics, Steady-State Stability of Synchronous Machines as Affected by. Concordia....687–90
Apparatus Bushings, A New Line of Oil Filled. Bowers, Johnston....729–32; disc. 733
Apparatus for Telephone Cables, Recent Improvements in Loading. Hale, Quinland, Ranges....385–92
Application of Low Frequency to Industrial Control Problems. Schmitz....1571–5; disc. 1575
Application on Power Systems, Feeder Voltage Regulator. Gosinski, Oberholtzer....1458–61; disc. 1461
Application of Precision, Snap-Acting Switches, The Characteristics and. Riche....1549–54; disc. 1554
Application of the Wheatstone Bridge to High-Speed Train Braking, A Unique. Hines....360–2
Applications, A 150-Kc Carrier System for Radio Relay. Boughtwood....577–82
Applications, Magnetic Amplifiers for Naval Shipboard. Buechler....1241–5; disc. 1245
Arc Behavior Near Current Zero by Means of Mathematical Models, A Study of A-C. Browne....141–50; disc. 150
Arc Furnace Duty, A Compressed Air Circuit Breaker for 23-Kv. Wilcox, Baker....154–8
Arc Power Converters in North America, Mercury. (Committee Report)....1031–59
Arc Rupturing Duty, A 230-Kv 3-Cycle Oil Circuit Breaker for Extra-Heavy. Leeds, Cushing....236–42; disc. 242
Arcing Fault Currents in Low-Voltage A-C Circuits. Wagner, Fountain....166–72; disc. 172
Area, Insulation Breakdown as a Function of. Hill, Schmidt....442–4; disc. 444
Armature With Six Adjustable Brushes, A Study of the 3-Phase Commutator. Franklin....197–204
Arresters' Impulse Spark-Over Volt-Time Characteristics, Expulsion-Vype Lightning. (Committee Report)....520
Articulated Cars for Test on Rapid Transit Division, Chicago Transit Authority, Three-Compartment. Otis....416–18
ASME-AIEE Standard Large 3,000-RPM Turbine Generators, Progress Report on. Mortensen, McClure, Lafloon....674–5; disc. 675
Attenuation for Microwave Measurements, A Standard of. Grantham, Freeman....329–35
Attenuator Materials, Attenuators and Terminations for Microwaves. Teal, Rigterink, Frosch....419–28
Automatic Air-Break Switches, Service Restoration With. Reardon....64–71; disc. 71
Automatic Pilot for Airplanes, An Induction Generator Used With the All-Electric. Vickers....182–5
Automatic Standing-Wave Indicator, An. Allen....1299–1302
Automatic Telephone Switching Systems, The "Director" for. Smith....611–19

B

Balance Telemeter, New Devices Derived From a Torque. Burnham....307–10
Balanced Fractional-Slot Wave Windings. Liwschitz....676–8
Band Broadcasting, A New 150-Kilowatt Transmitter for Standard. Boerner....943–51
Band Signal Generator, A Broad. Hahn, Ebert, Lynch....316–20
Barker, The Bellingham Hydraulic Log. Haner, Rose....1068–74
Basic Components, Electric Locomotives With Identical. Brecht, Kerr....339–43; disc. 343
(Basic Sciences) A Large-Scale General-Purpose Electric Analog Computer. Harder, McCann....664–73
(Basic Sciences) Attenuator Materials, Attenuators and Terminations for Microwaves. Teal, Rigterink, Frosch....419–28
(Basic Sciences) Bridge Erosion in Electrical Contacts and Its Prevention. Plann....1528–33
(Basic Sciences) Experimental Determination of the Capacitance of Heavy-Current Busses Comprised of Solid or Tubular Rectangular Conductors. Teasdale, Higgins....653–9; disc. 659
(Basic Sciences) Graphical Analysis of Control Systems. Evans....547–51
(Basic Sciences) Hystero-Viscosity in Silicone. Malti, Chatterjee....369–73
(Basic Sciences) Insulation Breakdown as a Function of Area. Hill, Schmidt....442–4; disc. 444
(Basic Sciences) Proximity Effect Factors for 3-Phase Coaxial Busses Comprised of Square Tubular Conductors. Higgins, Messinger....1538–9
(Basic Sciences) Solutions of the Mathieu Equation. Gray, Merwin, Brainerd....429–41
(Basic Sciences) Stabilized Permanent Magnets. Cioffi....1540–3
(Basic Sciences) "Terratex"—A Thin Flexible Inorganic Insulation. Walters....123–7
(Basic Sciences) The Magnetic Properties of Stainless Steels. Stein....1534–7
(Basic Sciences) The Space Charge Due to Corona. Smith....1137–44; disc. 1144
Bearings, Oil Film Thickness Indicator for Journal. Greenough....589–95; disc. 595
Behavior Near Current Zero by Means of Mathematical Models, A Study of A-C Arc. Browne....141–50; disc. 150
Behavior of Bundle Conductors, Results of Tests Carried Out at the 500-Kv Experimental Station of Chevilly (France), Especially on Corona. Cahen....1118–25; disc. 1125
Bellingham Hydraulic Log, The. Haner, Rose....1068–74
Beneficiation Plant, Power Distribution and Utilization in a Large Iron Ore. Gettelman....1726–32
Bibliography of Relay Literature 1944–1946. Committee Report....24–7
Blooming Mills, The Reversing Cycle of Modern. Montgomery, Sellers....1508–13; disc. 1513
Board of Directors, Report of the....1762–83
Bolted Aluminum-to-Copper Connections, An Experimental Investigation of the Electrical Performance of. Bonwitt....1208–18; disc. 1218
Braking, A Unique Application of the Wheatstone Bridge to High-Speed Train. Hines....360–2
Breakdown as a Function of Area, Insulation. Hill, Schmidt....442–4; disc. 444
Breakdown Strength of Electric-Cable Insulating Papers, The True Dielectric. Cloke, Bates....1191–5; disc. 1195
Breaker for Extra-Heavy Arc Rupturing Duty, A 230-Kv 3-Cycle Oil Circuit. Leeds, Cushing....236–42; disc. 242
Breaker for 23-Kv Arc Furnace Duty, A Compressed Air Circuit. Wilcox, Baker....154–8
Breaker, Improved Design of Low-Voltage Panel-Mounted Air Circuit. Sperow, Favre....695–8; disc. 698
Breaker Modernization and Faster Fault Clearing on Single-Phase Electrified Railroad, Circuit. Brown, Travers, Wood....705–13; disc. 713
Breaker, Performance Test of the Allgemeine Elektricitats Gesellschaft Free-Jet Air-Blast 220-Kv 2,500 Megavolt-Ampere Reclosing Circuit. Dovjikov, Diemond....295–304; disc. 304
Breaker Practice in the United States, A Brief Review of Switchgear and Circuit. Hobbs....893–7; disc. 897
Breakers for Grand Coulee Power Plant, Field Tests for Development of 10,000,000-Kva, 230-Kv Oil Circuit. Killgore, Clagett....271–83; disc. 283
Breakers, Large Indoor Power Air-Blast Circuit. Jansson....1675–8; disc. 1679
Breakers on Field Tests, Unusual Performance of Standard 230-Kv Impulse and Tank-Type Oil Circuit. Rietz....267–70; disc. 270
Bridge Erosion in Electrical Contacts and Its Prevention. Plann....1528–33
Bridge for Microwave Power Measurements, A Direct Reading D-C. Carlin, Blass....311–15
Bridge Method for Determining the Motional Characteristics of Permanent-Magnet Movable-Coil Instrument Mechanisms. Gilbert....411–15
Bridge to High-Speed Train Braking, A Unique Application of the Wheatstone. Hines....360–2
Brief Review of Switchgear and Circuit Breaker Practice in the United States, A. Hobbs....893–7; disc. 897
Broad-Band Signal Generator, A. Hahn, Ebert, Lynch....316–20
Broadcasting, A New 150-Kilowatt Transmitter for Standard Band. Boerner....943–51
Brush Wear, Effects of Silicone Vapor on. Marsden, Savage....1186–90
Brushes, A Study of the 3-Phase Commutator Armature With Six Adjustable. Franklin....197–204

Bundle Conductors, Results of Tests Carried Out at the 500-Kv Experimental Station of Chevilly (France), Especially on Corona Behavior of. Cahen.....1118–25; disc. 1125
Bus Designed for High-Capacity Generating Stations, A New Isolated-Phase Metal-Enclosed. Wyman, Shores.....699–703; disc. 703
Bus-Differential Protection Using Bushing Current Transformers, Instantaneous. Seeley, von Roeschlaub.....1709–18; disc. 1718
Bus for Grand Coulee Power Plant, Development of the 230-Kv Ring. Holmdahl, Killgore.....1369–78; disc. 1378
Bushing Current Transformers, Instantaneous Bus-Differential Protection Using. Seeley, von Roeschlaub.....1709–18; disc. 1718
Bushings, A New Line of Oil-Filled Apparatus. Bowers, Johnston.....729–32; disc. 733
Busses Comprised of Solid or Tubular Rectangular Conductors, Experimental Determination of the Capacitance of Heavy-Current. Teasdale, Higgins.....653–9; disc. 659
Busses Comprised of Square Tubular Conductors, Proximity Effect Factors for 3-Phase Coaxial. Higgins, Messinger.....1538–9
Button Switching in Telegraph Systems, Push. Blanchard, Blanton.....1733–40

C

Cable for Carrier Current Control Circuit, Polyethylene Insulated Coaxial. Slade, West.....1416–18; disc. 1419
Cable Installation at New Orleans, La., 115-Kv. High-Pressure Oil-Filled Pipe. Bullard, Pettee, Rhodes.....475–84; disc. 484
Cable Installation, Thermal Characteristics of a 120-Kv High-Pressure, Gas-Filled. Sanderson, Sticher, McGrath.....487–98; disc. 499
Cable Insulating Papers, The True Dielectric Breakdown Strength of Electric-. Cloke, Bates.....1191–5; disc. 1195
Cable Lines, Location of Gas Leaks in Pipe-Encased Gas Pressure. Piper.....10–21; disc. 21
Cable—Pipe Line Type, A 138,000-Volt Polyethylene-Sheathed Compression. McCormack, Hatcher, Wyatt, DelMar, Merrell, Palmer, DeTurk.....447–65; disc. 465
Cable, Statistical Methods as Applied to the Manufacture and Testing of Wire and. Woolfson.....752–4; disc. 754
Cable Temperature Problems—II, Use of Reduced-Scale Models for the Solutions of. Gemant, Sticher.....28–33; disc. 34
Cables, Effective Resistance and Inductance of 3-Conductor Shipyard Power. Summers.....1345–50
Cables in Steel Pipe or Conduit, Reactance of Large. Del Mar.....1409–12; disc. 1412
Cables, Recent Improvements in Loading Apparatus for Telephone. Hale, Quinlan, Ranger.....385–92
Cables, The Measurement and Investigation of Ionization Level of Rubber Insulated. Graham, Duffy, Foster.....1107–16; disc. 1116
Calculating Optimum Performance of Semiconductor Rectifiers, A Practical Approach. Wilson.....640–2; disc. 642
Calculation of Fault Currents, Simplified. (Committee Report).....1433–35
Calculation of Induction-Type Frequency Converters, Performance. Latzko.....691–4
Capacitance of Heavy-Current Busses Comprised of Solid or Tubular Rectangular Conductors, Experimental Determination of the. Teasdale, Higgins.....653–9; disc. 659
Capacitor for 66-Kv Transmission Line, Design and Protection of 10,000-Kva Series. Johnson, Marbury, Arthur.....363–7; disc. 368
Capacitor Improves Voltage on 66-Kv Line Supplying Large Electric Furnace Load, A 10,000-Kva Series. Jones, Arthur, Stearns, Johnson.....345–51; disc. 351
Capacitor Installation for Single-Phase Railway Service, Shunt. Brown, Witzke.....258–65; disc. 265
Capacitor Substation, Design and Layout of 66-Kv 10,000-Kva Series. Miller.....355–9
Capacitors and Traps for Rural Line Carrier, Coupling. (Committee Report).....1426–8
Carbon Pile Voltage Regulator for Aircraft Generators, Analysis and Redesign of a. Kouwenhoven, Thaler.....1197–1202; disc. 1202
Carrier Channels for Telemetering. Talmage.....1448–56; disc. 1456
Carrier, Coupling Capacitors and Traps for Rural Line. (Committee Report).....1426–8
Carrier-Current Channels, A Faster Telemeter for. Lynch, Thomas, Lunge.....288–94; disc. 294
Carrier Current Control Circuit, Polyethylene Insulated Coaxial Cable for. Slade, West.....1416–18; disc. 1419
Carrier-Current Equipment for Telemetering and Load Control, Characteristics of New. Beckwith.....1649–52; disc. 1652
Carrier-Current Frequencies, Report on Method of Measurements at. (Committee Report).....1429–32; disc. 1432
(Carrier Current) Relaying Difficulties Disclosed by Staged-Fault Tests. Morgan, Evans.....73–82
Carrier System, Filters for a 150-Kc. Taylor.....583–8
Carrier System for Radio Relay Applications, A 150-Kc. Boughtwood.....577–82
Carrier Telemetering and Load Control, System Operation Improved With. Walton, Lennser.....1643–7; disc. 1647
Carrier, Telemetering Circuits—Metallic and. Bostwick.....1081–6; disc. 1086
Carrying Load, Measuring Transformer Winding Temperatures Continuously With the Transformer. Lockie, Stein.....1608–16; disc. 1616
Cars for Test on Rapid Transit Division, Chicago Transit Authority, Three-Compartment Articulated. Otis.....416–18
Cathode Materials for Power Tubes, Amalgam. Lyon, Williams.....627–30
Cathode-Ray Oscillograph, The Naval Ordnance Laboratory Six-Trace. Edwards.....1220–23
Causes and Effects of Stray Electric Currents in Coal Mines. Harrison.....1759–61
Central Utility Power Service Versus Local Plant Generation in Industry. Frampton.....880–3; disc. 884
Ceramics as Influenced by Temperature, Electrical Properties of. Lindsay, Berberich.....734–41; disc. 741
Change of Frequency on the System of the Southern California Edison Company. Tice, Kronenberg, Johnson, Enefer, Tugby, Sidway.....809–25; disc. 825
Changer, Suddenly Applied Loads Carried by a Variable-Ratio Synchronous-Induction Frequency. Darling, Kaufman.....91–4
Channels, A Faster Telemeter for Carrier-Current. Lynch, Thomas, Lunge.....288–94; disc. 294
Channels for Operation of Supervisory Control Equipment. Derr, Brown.....1654–60
Channels for Telemetering, Carrier. Talmage.....1448–56; disc. 1456
Characteristics and Application of Precision, Snap-Acting Switches, The. Riche.....1549–54; disc. 1554
Characteristics, Expulsion-Type Lightning Arresters' Impulse Spark-Over Volt-Time. (Committee Report).....520
Characteristics of a 120-Kv High-Pressure, Gas-Filled Cable Installation, Thermal. Sanderson, Sticher, McGrath.....487–99; disc. 499
Characteristics of Dry-Type Transformer Insulation at High Temperature, Aging. Stewart, Whitman.....1600–06; disc. 1607
Characteristics of New Carrier-Current Equipment for Telemetering and Load Control. Beckwith.....1649–52; disc. 1652
Characteristics of Permanent-Magnet Movable-Coil Instrument Mechanisms, A Bridge Method for Determining the Motional. Gilbert.....411–15
Characteristics of Recording Instruments, Frequency Response. Graybeal.....755–66
Charge Due to Corona, The Space. Smith.....1137–44; disc. 1144
(Chemical) Electrification of Petroleum Pipe Lines. Hyde.....968–74; disc. 974
(Chemical) Oil Production by Electric Power. Taylor.....977–86; disc. 986
Chemical Rate Phenomenon, Electrical Insulation Deterioration Treated as a. Dakin.....113–18; disc. 118
(Chemical) Twenty-Five Years of Copper—Copper Oxide Rectifiers. Grondahl.....403–10
Chevilly (France), Especially on Corona Behavior of Bundle Conductors, Results of Tests Carried Out at the 500-Kv Experimental Station of. Cahen.....1118–25; disc. 1125
Chicago Transit Authority, Three-Compartment Articulated Cars for Test on Rapid Transit Division. Otis.....416–18
Chorded or Doubly Shifted Fractional-Slot Lap and Wave Windings, Doubly. Liwschitz.....684–6
Circuit Breaker for Extra-Heavy Arc Rupturing Duty, A 230-Kv 3-Cycle Oil. Leeds, Cushing.....236–42; disc. 242
Circuit Breaker for 23-Kv Arc Furnace Duty, A Compressed Air. Wilcox, Baker.....154–8
Circuit Breaker, Improved Design of Low-Voltage Panel-Mounted. Sperow, Favre.....695–8; disc. 698
Circuit Breaker Modernization and Faster Fault Clearing on Singel-Phase Electrified Railroad. Brown, Travers, Wood.....705–13; disc. 713
Circuit Breaker, Performance Test of the Allgemeine Elektricitats Gesellschaft Free-Jet Air-Blast 220-Kv 2,500-Megavolt-Ampere Reclosing. Dovjikov, Diemond.....295–304; disc. 304
Circuit Breaker Practice in the United States, A Brief Review of Switchgear. Hobbs.....893–7; disc. 897
Circuit Breakers for Grand Coulee Power Plant, Field Tests for Development of 10,000,000-Kva, 230-Kv Oil. Killgore, Clagett.....271–83; disc. 283
Circuit Breakers, Large Indoor Power Air-Blast. Jansson.....1675–8; disc. 1679
Circuit Breakers on Field Tests, Unusual Performance of Standard 230-Kv Impulse and Tank-Type Oil. Rietz.....267–70; disc. 270
Circuit for Aircraft Reverse-Current Cutout, Proposed. Marzolf.....1246–8
Circuit, Polyethylene Insulated Coaxial Cable for Carrier Current Control. Slade, West.....1416–18; disc. 1419
Circuit, Relation Between Electrical and Mechanical Parameters of a Permanent-Magnet Movable-Coil Instrument Having a General Circuit. Goodwin.....374–9
Circuits, Arcing Fault Currents in Low-Voltage A-C. Wagner, Fountain.....166–72; disc. 172
Circuits in Telephone Switching, Relay Preference Lockout. Joel.....1720–5; disc. 1725
Circuits—Metallic and Carrier, Telemetering. Bostwick.....1081–6; disc. 1086
Circuits of a Supersonic Reflectoscope, Electronic. DeLano.....128–37
Circuits of Synchronous and Induction Machines, Steady-State Equivalent. Kron.....75–81
Circuits, Voltage Stresses in Distribution Transformers Due to Lightning Currents in Low-Voltage. Beardsley, McMorris, Stewart.....1632–5; disc. 1635
Circuits, Voltage Surges in Relay Control. Halman, Harris.....1693–9; disc. 1699
Clamps for Aluminum Conductors, Joints and. Tebo.....1145–50; disc. 1150
Clutch, The Magnetic Fluid. Rabinow.....1308–15
Coach Distribution System, Trolley. McDonald.....393–402; disc. 402
Coal Mines, Causes and Effects of Stray Electric Currents in. Harrison.....1759–61
Coal, Residual Oil, Diesel Oil, and Electricity as Energy Sources for Motive Power Operation in the Pacific Northwest, The Present Competitive Position of. Martin.....1664–9
Coaxial Buses Comprised of Square Tubular Conductors, Proximity Effect Factors for 3-Phase. Higgins, Messinger.....1538–9
Coaxial Cable for Carrier Current Control Circuit, Polyethylene Insulated. Slade, West.....1416–18; disc. 1419
Coaxial Telephone and Television Systems, Progress in. Abraham.....1520–7
Coil Instrument Having a General Circuit, Relation Between Electrical and Mechanical Parameters of a Permanent-Magnet Movable. Goodwin.....374–9
Coil Instrument Mechanisms, A Bridge Method for Determining the Motional Characteristics of Permanent-Magnet Movable. Gilbert.....411–15
Coils on Shipboard Magnetic Compasses by Use of Compass-Compensating Coils, Compensation of Effects of Degaussing. Robinson.....1278–81
Cold-Rolled Strip Steel, X-Ray Thickness Gauge for. Lundahl.....83–90
Cold Strip Reduction Mills, Electric Equipment. Miller.....133–9; disc. 139
Colorado Rockies, Pumping for Power in the. Wilson.....1127–36
(Commercial) The Heat Pump From the Utility's Point of View. Andrews.....562–4
(Committee Report) Bibliography of Relay Literature 1944–46.....24–7
(Committee Report) Coupling Capacitors and Traps for Rural Line Carrier.....1426–8
(Committee Report) Expulsion-Type Lightning Arresters' Impulse Spark-Over Volt-Time Characteristics.....520
(Committee Report) Mercury-Arc Power Converters in North America.....1031–59
(Committee Report). Power System Overvoltages Produced by Faults and Switching Operations.....1720–21; disc. 921
(Committee Report) Report on Method of Measurements at Carrier-Current Frequencies.....1429–32; disc. 1432
(Committee Report) Simplified Calculation of Fault Currents.....1433–35
(Committee Report) Survey of Lightning Protective Equipment for Rotating A-C Machines.....516–19; disc. 519
Committees and Officers for 1948–49.....1784–98
(Communication) A New 150-Kilowatt Transmitter for Standard Band Broadcasting. Boerner.....943–51
(Communication) A 150-Kc Carrier System for Radio Relay Applications. Boughtwood.....577–82
(Communication) A Telegraph Signal Analyzer. Erickson.....380–4; disc. 384
(Communication) A Turn-In-Gap Erase Head for Magnetic Recorders Providing Intense High-Frequency Fields. Wiegand, Zenner.....507–10
(Communication) An Electroacoustical System. Walker.....35–40; disc. 40
(Communication) An Optical Radar for Surveying. Hansen.....660–3
(Communication) Attenuator Materials, Attenuators and Terminations for Microwaves. Teal, Rigterink, Frosch.....419–28

(Communication) Crystal Filters Using Ethylene Diamine Tartrate in Place of Quartz. Willis . 552–6
(Communication) Design and Performance of Ethylene Diamine Tartrate Crystal Units. Griffin, Pennell . . 557–61
(Communication) Facsimile Transmission for Pickup and Delivery of Telegrams. Ridings 1293–8
(Communication) FCC Diathermy Design for Low Harmonic Radiation and Good Frequency Stability. Chapin, Roberts, Mobley . . . . . 42–6; disc. 46
(Communication) Filters for a 150-Kc Carrier System. Taylor 583–8
(Communication) Frequency Modulation Receiver Design Trends. Young 1514–19
(Communication) Growing Crystals of Ethylene Diamine Tartrate. Walker, Kohman . . . . . 565–70; disc. 570
(Communication) Magnetic Recording Tapes. Camras 503–06
(Communication) Military Teletypewriter Systems of World War II. Singer 1398–1408
(Communication) Mobile Radio. Bailey . . . . . 923–31; disc. 932
(Communication) Push Button Switching in Telegraph Systems. Blanchard, Blanton 1733–40
(Communication) Progress in Coaxial Telephone and Television Systems. Abraham 1520–7
(Communication) Radio for Telephone Service in America. Romnes 1060–7
(Communication) Recent Improvements in Loading Apparatus for Telephone Cables. Hale, Quinlan, Ranges 385–92
(Communication) Relay Preference Lockout Circuits in Telephone Switching. Joel . . . . 1720–5; disc. 1725
(Communication) Television Receiving Systems. Sunnett 1544–8
(Communication) The "Director" for Automatic Telephone Switching Systems. Smith 611–19
(Communication) Western Union Teletape Facsimile. Pollard 511–15
Commutator Armature With Six Adjustable Brushes, A Study of the 3-Phase. Franklin 197–204
Comparative Operating Results of Steam, Diesel-Electric, and Electric Motive Power on the Great Northern Railway Electrification. Gaynor . . . . . 231–4; disc. 234
Compartment Articulated Cars for Test on Rapid Transit Division, Chicago Transit Authority, Three. Otis 416–18
Compasses by Use of Compass-Compensating Coils, Compensation of Effects of Degaussing Coils on Shipboard Magnetic. Robinson 1278–81
Compensation of Effects of Degaussing Coils on Shipboard Magnetic Compasses by Use of Compass-Compensating Coils. Robinson 1278–81
Competitive Position of Coal, Residual Oil, Diesel Oil, and Electricity as Energy Sources for Motive Power Operation in the Pacific Northwest, The Present. Martin 1664–9
Components, Electric Locomotives With Identical Basic. Brecht, Kerr . . . . . 339–43; disc. 343
Compressed Air Circuit Breaker for 23-Kv Arc Furnace Duty, A. Wilcox, Baker 154–8
Compression Cable—Pipe Line Type, A 138,000-Volt Polyethylene-Sheathed. McCormack, Hatcher, Wyatt, DelMar, Merrell, Palmer, DeTurk . . . . . 447–65; disc. 465
Computer, A Large-Scale General-Purpose Electric Analog. Harder, McCann 664–73
Concept of Contact Performance, A New Outdoor Air Switch and a New. Killian . . . . 1382–7; disc. 1387
Condensing Steam Turbine-Generators, Speed Governing Design Considerations for Multivalve. Barnett . . . . . 1557–61; disc. 1561
Conductor Shipyard Power Cables, Effective Resistance and Inductance of 3-. Summers 1345–50
(Conductors) A 138,000-Volt Polyethylene-Sheathed Compression Cable—Pipe Line Type. McCormack, Hatcher, Wyatt, DelMar, Merrell, Palmer, DeTurk . . . . . 447–65; disc. 465
Conductors, Experimental Determination of the Capacitance of Heavy-Current Busses Comprised of Solid or Tubular Rectangular Conductors, Teasdale, Higgins . . . . . 653–9; disc. 659
Conductors in Steel Pipe or Conduit, A-C Resistance of Large Size. Wiseman . . . . . 1745–52; disc. 1752
Conductors, Joints and Clamps for Aluminum. Tebo . . . . . 1145–50; disc. 1150
(Conductors) 115-Kv High-Pressure Oil-Filled Pipe Cable Installation at New Orleans, La. Bullard, Pettee, Rhodes . . . . . 475–84; disc. 484
Conductors, Problems in the Measurement of A-C Resistance and Reactance of Large. Salter . . . . . 1390–6; disc. 1396
Conductors, Proximity Effect Factors for 3-Phase Coaxial Buses Comprised of Square Tubular. Higgins, Messinger 1538–9
Conductors, Relative Surface Voltage Gradients of Grouped. Temoshok . . . . . 1583–9; disc. 1589
Conductors, Results of Tests Carried Out at the 500-Kv Experimental Station of Chevilly (France), Especially on Corona Behavior of Bundle. Cahen . . . . . 1118–25; disc. 1125
(Conductors) Thermal Characteristics of a 120-Kv High-Pressure, Gas-Filled Cable Installation. Sanderson, Sticher, McGrath . . . . . 487–98; disc. 499
Conduit, A-C Resistance of Large Size Conductors in Steel Pipe or. Wiseman . . . . . 1745–52; disc. 1752
Conduit, Reactance of Large Cables in Steel Pipe or. Del Mar . . . . . 1409–12; disc. 1412
Connections, An Experimental Investigation of the Electrical Performance of Bolted Aluminum-to-Copper. Bonwitt . . . . . 1208–18; disc. 1218
Consideration of System-Wide Load Divisions by Means of Accurate Time Control, Preliminary. Curtis, Pickslay . . . . . 1562–9; disc. 1569
Considerations for Multivalve Condensing Steam Turbine-Generators, Speed Governing Design. Barnett . . . . . 1557–61; disc. 1561
Contact Performance, A New Outdoor Air Switch and a New Concept of. Killian . . . . 1382–7; disc. 1387
Contact Protection Systems, Sensitive Relay. Dallas, McCully 1204–07
Contacts and Its Prevention, Bridge Erosion in Electrical. Pfann 1528–33
Contaminated Insulators in Fog, Performance of Dust-, Cozzens, Blakeslee . . . . . 1686–91; disc. 1691
Contamination, Flashovers of Suspension Insulators Due to. Adler, Wickham, Oldacre . 1680–3; disc. 1683
Contamination, Insulator Surface. Frey . . . . . 1420–4; disc. 1424
Contamination, Pole Fires Due to Insulator. Wickham, Adler, Oldacre 1741–4
Continuous Load-Frequency Control for Interconnected Power Systems. Dimond, Lunge . . . . . 1483–8; disc. 1488
Control, Characteristics of New Carrier-Current Equipment for Telemetering and Load. Beckwith . . . . . 1649–52; disc. 1652
Control Circuit, Polyethylene Insulated Coaxial Cable for Carrier Current. Slade, West . . . . . 1416–18; disc. 1419
Control Circuits, Voltage Surges in Relay. Halman, Harris . . . . . 1693–9; disc. 1699
Control, Dynamic Lowering D-C Hoist. Pettit . . . . . 1576–80; disc. 1581
Control Element, A Polarized Relay as an Aircraft. Johnson, Glasow 1249–55
Control Equipment, Channels for Operation of Supervisory. Derr, Brown 1654–60
Control for Interconnected Power Systems, Continuous Load-Frequency. Dimond, Lunge . . . . . 1483–8; disc. 1488
Control for Shovels and Draglines, Evolution of Ward-Leonard. Stevens 1491–7
Control for System Loads, Emergency. Comly, Kelley, McCormack, Phillips, Schroeder . . . . . 1474–81; disc. 1482
Control of Wound Rotor Induction Motors, The Liquid Rheostat for Speed. McFarland, Alvarez . . . . . 603–09; disc. 609
Control, Preliminary Consideration of System-Wide Load Division by Means of Accurate Time. Curtis, Pickslay . . . . . 1562–9; disc. 1569
Control Problems, Application of Low Frequency to Industrial. Schmitz . . . . . 1571–5; disc. 1575
Control System for a Multijet Airplane, Starter-Generator. Hart 1316–18
Control, System Operation Improved With Carrier Telemetering and Load. Walton, Lenner . . . . . 1643–7; disc. 1647
Control Systems, Graphical Analysis of. Evans . 547–51
Control Without Feeder Voltage Regulators, Power System Voltage. Smeloff . . . . . 1462–4; disc. 1465
Controllers, Improvements in Rolling Mill Preset Screw-Down. Leitch, Schurr 58–63
Conversion and Transmission Costs, Railroad Electrification Energy. Kimball, Holm . 219–26; disc. 227
Converter for Induction Heating of Metals, Mercury-Arc Frequency. Durand, Rice 1592–9
Converters in North America, Mercury Arc Power. (Committee Report) 1031–59
Converters, Performance Calculation of Induction-Type Frequency. Latzko 691–4
Copper Connections, An Experimental Investigation of the Electrical Performance of Bolted Aluminum-to-, Bonwitt . . . . . 1208–18; disc. 1218
Copper—Copper Oxide Rectifiers, Twenty-Five Years of. Grondahl 403–10
Copper Mining, Utilization of Electric Power in Open-Pit. French, Speight . . . . . 956–66; disc. 966
Core Form Upon the Iron Losses of Transformers, Influence of the. Stein . . . . . 95–103; disc. 103
Corona Behavior of Bundle Conductors, Results of Tests Carried Out at the 500-Kv Experimental Station of Chevilly (France), Especially on. Cahen . . . . . 1118–25; disc. 1125
Corona, The Space Charge Due to. Smith . . . . . 1137–44; disc. 1144
Costs, Power, and the Contribution of Existing Transmission Networks Towards Cost Reduction of Power for Electrification of Main Line Railroads with Moderate Traffic. Evans . . . . . 596–8; disc. 599
Costs, Railroad Electrification Energy Conversion and Transmission. Kimball, Holm . . 219–26; disc. 227
Costs Retarding Railroad Electrification, Are the Overhead Distribution? Birch . . . . . 243–55; disc. 255
Coulomb Friction on the Performance of Servomechanisms, The Effect of. McCann, Lindvall, Wilts 540–6
Coupling Capacitors and Traps for Rural Line Carrier. (Committee Report) 1426–8
Crystal Filters Using Ethylene Diamine Tartrate in Place of Quartz. Willis 552–6
Crystal Units, Design and Performance of Ethylene Diamine Tartrate. Griffin, Pennell 557–61
Crystals of Ethylene Diamine Tartrate, Growing. Walker, Kohman . . . . . 565–70; disc. 570
Current Channels, A Faster Telemeter for Carrier. Lynch, Thomas, Lunge . . . . . 288–94; disc. 294
Current Control Circuit, Polyethylene Insulated Coaxial Cable for Carrier. Slade, West . . . . . 1416–18; disc. 1419
Current Cutout, Proposed Circuit for Aircraft Reverse-. Marzolf 1246–8
Current Equipment for Telemetering and Load Control, Characteristics of New Carrier-. Beckwith . . . . . 1649–52; disc. 1652
Current Frequencies, Report on Method of Measurements at Carrier-. (Committee Report) . . . . . 1429–32; disc. 1432
Current Transformers, Instantaneous Bus-Differential Protection Using Bushing. Seeley, von Roeschlaub . . . . . 1709–18; disc. 1718
Current Zero by Means of Mathematical Models, A Study of A-C Arc Behavior Near. Browne . . . . . 141–50; disc. 150
Currents in Coal Mines, Causes and Effects of Stray Electric. Harrison 1759–61
Currents in Low-Voltage A-C Circuits, Arcing Fault. Wagner, Fountain . . . . . 166–72; disc. 172
Currents in Low-Voltage Circuits, Voltage Stresses in Distribution Transformers Due to Lightning. Beardsley, McMorris, Stewart . . 1632–5; disc. 1635
Currents, Simplified Calculation of Fault. (Committee Report) 1433–35
Cutout, Proposed Circuit for Aircraft Reverse-Current. Marzolf 1246–8
Cycle of Modern Blooming Mills, The Reversing. Montgomery, Sellers . . . . . 1508–13; disc. 1513
Cycles, A Precision Electrothermic Voltmeter for Measurements Between 20 and 20,000. Hermach 1224–7

D

Degaussing Coils on Shipboard Magnetic Compasses by Use of Compass-Compensating Coils, Compensation of Effects of. Robinson 1278–81
Degaussing Installations for Protection Against Magnetic Mines, Shipboard. Michel . . . . 1270–5; disc. 1275
Deionization Times of Thyratron Tubes, A Method for the Measurement of the Ionization and. Birnbaum 209–14
Delivery of Telegrams, Facsimile Transmission for Pickup and. Ridings 1293–8
Deposits, Insulators to Withstand Air-Borne. Taylor . . . . . 1436–41; disc. 1441
Depth of Sea Water, An Instrument for Recording Continuously the Salinity, Temperature, and. Jacobson 714–22
Design and Layout of 66-Kv 10,000-Kva Series Capacitor Substation. Miller 355–9
Design and Performance of Ethylene Diamine Tartrate Crystal Units. Griffin, Pennell 557–61
Design and Protection of 10,000-Kva Series Capacitor for 66-Kv Transmission Line. Johnson, Marbury, Arthur . . . . . 363–7; disc. 368
Design Considerations for Multivalve Condensing Steam Turbine-Generators, Speed Governing. Barnett . . . . . 1557–61; disc. 1561
Design for Low Harmonic Radiation and Good Frequency Stability, FCC Diathermy. Chapin, Roberts, Mobley . . . . . 42–6; disc. 46
Design Information, A Method of Selecting Inherent Overheat Protectors Based Upon Motor. Vaughan . . . . . 1023–9; disc. 1030
Design, Modern Trends in Hydraulic Turbine. Rheingans 1075–80
Design of Low-Voltage Panel-Mounted Air Circuit Breaker, An Improved. Sperow, Favre . . . . . 695–8; disc. 698
Design Trends, Frequency Modulation Receiver. Young 1514–19
Detection Methods, Experience with Transformer Impulse Failure. Aicher . . . . . 1621–7; disc. 1627
Detectors for Measurements, Primary. Lynch, Corson 843–53
Deterioration Treated as a Chemical Rate Phenomenon, Electrical Insulation. Dakin . . . 113–18; disc. 118
Determination of the Capacitance of Heavy-Current Buses Comprised of Solid or Tubular Rectangular Conductors, Experimental. Teasdale, Higgins . . . . . 653–9; disc. 659

Development in Mexico, Power. Urquidi, Del Busto, Lozano....841–2
Development of a Metropolitan Electric System, Planning the. Waring....1467–72; disc. 1472
Development of 10,000,000-Kva 230-Kv Oil Circuit Breakers for Grand Coulee Power Plant, Field Tests for. Killgore, Clagett....271–83; disc. 283
Development of the Transmission System From the Grand Coulee Power Plant. Hoard, Helwith....1095–1100; disc. 1100
Development of the 230-Kv Ring Bus for Grand Coulee Power Plant. Holmdahl, Killgore....1369–78; disc. 1378
Development, The Grand Coulee Power. Denton....899–910; disc. 911
Developments in the Pulp and Paper Industry, Electrical. Baker....827–34; disc. 834
Devices Derived From a Torque Balance Telemeter, New. Burnham....307–10
Devices on Diesel-Electric Locomotives, Speed-Responsive. Johanson....336–8
Diamine Tartrate Crystal Units, Design and Performance of Ethylene. Griffin, Pennell....557–61
Diamine Tartrate, Growing Crystals of Ethylene. Walker, Kohman....565–70; disc. 570
Diamine Tartrate in Place of Quartz, Crystal Filters Using Ethylene. Willis....552–6
Diathermy Design for Low Harmonic Radiation and Good Frequency Stability, FCC. Chapin, Roberts, Mobley....42–6; disc. 46
Dielectric Breakdown Strength of Electric-Cable Insulating Papers, The True. Cloke, Bates....1191–5; disc. 1195
(Dielectric) Electrical Properties of Ceramics as Influenced by Temperature. Lindsay, Berberich....734–41; disc. 741
Dielectric Heating, Induction and. Scott....885–92; disc. 892
Diesel-Electric, and Electric Motive Power on the Great Northern Railway Electrification, Comparative Operating Results of Steam. Gaynor....231–4; disc. 234
Diesel-Electric Locomotives, Short Time Ratings of. Campbell, Woods....1661–3
Diesel-Electric Locomotives, Speed-Responsive Devices on. Johanson....336–8
Diesel Oil, and Electricity as Energy Sources for Motive Power Operation in the Pacific Northwest, The Present Competitive Position of Coal, Residual Oil. Martin....1664–9
Differential Protection Using Bushing Current Transformers, Instantaneous Bus-. Seeley, von Roeschlaub....1709–18; disc. 1718
Difficulties Disclosed by Staged-Fault Tests, Relaying. Morgan, Evans....73–82
D-C Amplifier Stabilized for Zero and Gain. Williams, Tarpley, Clark....47–57
D-C Bridge for Microwave Power Measurements, A Direct Reading. Carlin, Blass....311–15
D-C Generators, Steady-State Analysis of Aircraft. Van Valkenburg, Matthews....1351–8
D-C Hoist Control, Dynamic Lowering. Pettit....1576–80; disc. 1581
D-C Motors from Controlled Rectifiers, Operation of Large. Schmidt, Smith....679–83
Direct Reading D-C Bridge for Microwave Power Measurements, A. Carlin, Blass....311–15
"Director" for Automatic Telephone Switching Systems, The. Smith....611–19
Distance Energy Transmission, Economics of Long. Pierce, George....1089–94; disc. 1094
Distance Ground Relay, A New. Goldsborough....1442–6; disc. 1446
Distance Relay, A New Reactance. Dewey, McGlynn....743–6; disc. 746
Distribution and Utilization in a Large Iron Ore Beneficiation Plant, Power. Gettelman....1726–32
Distribution Costs Retarding Railroad Electrification, Are the Overhead? Birch....243–55; disc. 255
(Distribution) Location of Gas Leaks in Pipe-Encased Gas Pressure Cable Lines. Piper....10–21; disc. 21
(Distribution) Recent Improvements in Loading Apparatus for Telephone Cables. Hale, Quinlan, Ranges....385–92
Distribution System, Trolley Coach. McDonald....393–402; disc. 402
Distribution Systems, Selective Tripping Arrangements for Protection of Ship's A-C Electric. Cole....1256–62; disc. 1262
Distribution Systems, Trends and Practices in Modern Industrial Power. Bloomquist....872–9; disc. 879
Distribution Transformers Due to Lightning Currents in Low-Voltage Circuits, Voltage Stresses in. Beardsley, McMorris, Stewart....1632–5; disc. 1635
Distribution Voltages, Rural. Edmunds, Roloson....1324–6; disc. 1326
Divisions by Means of Accurate Time Control, Preliminary Consideration of System-Wide Load. Curtis, Pickslay....1562–9; disc. 1569
(Domestic) The Characteristics and Application of Precision, Snap-Acting Switches. Riche....1549–54; disc. 1554
(Domestic) The Heat Pump From the Utility's Point of View. Andrews....562–4
Doubly-Chorded or Doubly Shifted Fractional-Slot Lap and Wave Windings. Liwschitz....684–6
Draglines, Electric Equipment for Power Shovels and. Schwedes, Stoetzel....1498–1506; disc. 1507
Draglines, Evolution of Ward-Leonard Control for Shovels and. Stevens....1491–7
Drive, Electronic Speed Regulators for Sectional Paper Machine. Baker, Kovalsky....1636–42
Dry-Type Transformer Insulation at High Temperature, Aging Characteristics of. Stewart, Whitman....1600–06; disc. 1607
Dust-Contaminated Insulators in Fog, Performance of. Cozzens, Blakeslee....1686–91; disc. 1691
Duty, A Compressed Air Circuit Breaker for 23-Kv Arc Furnace. Wilcox, Baker....154–8
Duty, A 230-Kv 3-Cycle Oil Circuit Breaker for Extra-Heavy Arc Rupturing. Leeds, Cushing....236–42; disc. 242
Dynamic Lowering D-C Hoist Control. Pettit....1576–80; disc. 1581

Magnetic Suspension of the Watt-Hour Meter Rotor. Trekell, Mendelsohn, Wright....1180–5; disc. 1185
Magnets, Stabilized Permanent. Cioffi.....1540–3
Main Exciter Rototrol Excitation For Turbine Generators. Lynn, Valentine.....535–9; disc. 539
Manufacture and Testing of Wire and Cable, Statistical Methods as Applied to the. Woolfson.....752–4; disc. 754
(Marine Transportation) Compensation of Effects of Degaussing Coils on Shipboard Magnetic Compasses by Use of Compass-Compensating Coils. Robinson.....1278–81
(Marine Transportation) Effective Resistance and Inductance of 3-Conductor Shipyard Power Cables. Summers.....1345–50
(Marine Transportation) Electric Propulsion in Naval, Surface Vessels. Jucarone....1329–39; disc. 1340
(Marine Transportation) Functional Evaluation of Insulating Materials. Mathes....1236–9; disc. 1240
(Marine Transportation) Magnetic Amplifiers for Naval Shipboard Applications. Buechler.....1241–5; disc. 1245
(Marine Transportation) Overload Protection of Silicone-Insulated Motors for Shipboard Use. Grigg, Watkins.....1341–4; disc. 1344
(Marine Transportation) Selective Tripping Arrangements for Protection of Ship's A-C Electric Distribution Systems. Cole.....1256–62; disc. 1262
(Marine Transportation) Shipboard Degaussing Installations for Protection Against Magnetic Mines. Michel.....1270–5; disc. 1275
(Marine Transportation) Silicone Insulation in Submarines—Toxicity. Walker, Shea.....1232–5
(Marine Transportation) Use of Propulsion Generators on Naval Vessels to Supply Shore Power. Anderson, Fifer.....1282–7; disc. 1287
(Marine Transportation) Ventilation of Rotating Electrical Equipment on Shipboard. Harrison.....1263–9; disc. 1269
Materials, Attenuators and Terminations for Microwaves, Attenuator. Teal, Rigterink, Frosch. 419–28
Materials, Functional Evaluation of Insulating. Mathes.....1236–9; disc. 1240
Mathematical Models, A Study of A-C Arc Behavior Near Current Zero by Means of. Browne.....141–50; disc. 150
Mathieu Equation, Solutions of the. Gray, Merwin, Brainerd.....429–41
Measurement and Investigation of Ionization Level of Rubber Insulated Cables, The. Graham, Duffy, Foster.....1107–16; disc. 1116
Measurement of A-C Resistance and Reactance of Large Conductors, Problems in the. Salter.....1390–6; disc. 1396
Measurement of Interference From Radio-Frequency Heating Equipment. Brown.....1102–06
Measurement of the Ionization and De-Ionization Times of Thyratron Tubes, A Method for the. Birnbaum.....209–14
Measurements, A Direct Reading D-C Bridge for Microwave Power. Carlin, Blass.....311–15
Measurements, A Standard of Attenuation for Microwave. Grantham, Freeman.....329–35
Measurements and Standards, Microwave Frequency. Husten, Lyons.....321–8
Measurements at Carrier-Current Frequencies, Report on Method of. (Committee Report).....1429–32; disc. 1432
Measurements Between 20 and 20,000 Cycles, A Precision Electrothermic Voltmeter for. Hermach.....1224–7
(Measurements) Primary Detectors for Measurements. Lynch, Corson.....843–53
Measuring Transformer Winding Temperatures Continuously with the Transformer Carrying Load. Lockie, Stein.....1608–16; disc. 1616
Mechanical Parameters of a Permanent-Magnet Movable-Coil Instrument Having a General Circuit, Relation Between Electrical and. Goodwin...374–9
Mechanisms, A Bridge Method for Determining the Motional Characteristics of Permanent-Magnet Movable-Coil Instrument. Gilbert.....411–15
Mercury-Arc Frequency Converter for Induction Heating of Metals. Durand, Rice.....1592–9
Mercury-Arc Power Converters in North America. (Committee Report).....1031–59
(Metal) Causes and Effects of Stray Electric Currents in Coal Mines. Harrison.....1759–61
(Metal) Electric Equipment for Power Shovels and Draglines. Schwedes, Stoetzel...1498–1506; disc. 1507
Metal-Enclosed Bus Designed for High-Capacity Generating Stations, A New Isolated-Phase. Wyman, Shores.....699–703; disc. 703
(Metal) Evolution of Ward-Leonard Control for Shovels and Draglines. Stevens.....491–7
(Metal Industry) An X-Ray Thickness Gauge for Hot-Strip Rolling Mills. Clapp, Pohl.....620–6
(Metal) Power Distribution and Utilization in a Large Iron Ore Beneficiation Plant. Gettelman..1726–32
Metallic and Carrier, Telemetering Circuits—. Bostwick.....1081–6; disc. 1086
Metals, Mercury-Arc Frequency Converter for Induction Heating of. Durand, Rice.....1592–9
Meter Rotor, Magnetic Suspension of the Watt-Hour. Trekell, Mendelsohn, Wright....1180–5; disc. 1185
Method for Determining the Motional Characteristics of Permanent-Magnet Movable-Coil Instrument Mechanisms, A Bridge. Gilbert.....411–15
Method for the Measurement of the Ionization and De-ionization Times of Thyratron Tubes, A. Birnbaum.....209–14
Method of Measurements at Carrier-Current Frequencies, Report on. (Committee Report).....1429–32; disc. 1432
Method of Power Network Analysis, The General Solution. Dunstan.....631–8; disc. 638
Method of Selecting Inherent Overhead Protectors Based Upon Motor Design Information, A. Vaughan.....1023–9; disc. 1030
Methods as Applied to the Manufacture and Testing of Wire and Cable, Statistical. Woolfson.....752–4; disc. 754
Methods, Experience with Transformer Impulse Failure Detection. Aicher.....1621–7; disc. 1627
Metropolitan Electric System, Planning the Development of a. Waring.....1467–72; disc. 1472
Mexico, Hydroelectric Potentiality of. Quintero.....993–4
Mexico, Power Development in. Urquidi, Del Busto, Lozano.....841–2
Mexico's Hydraulic Resources Through Multiple Purposes, Full Utilization of. Alba.....989–92
(Mica) Electrical Properties of Ceramics as Influenced by Temperature. Lindsay, Berberich.....734–41; disc. 741
Microwave Frequency Measurements and Standards. Husten, Lyons.....321–8
Microwave Measurements, A Standard of Attenuation for. Grantham, Freeman.....329–35
Microwave Power Measurements, A Direct Reading D-C Bridge for. Carlin, Blass.....311–15
Microwaves, Attenuator Materials, Attenuators and Terminations for. Teal, Rigterink, Frosch. 419–28
Military Teletypewriter Systems of World War II. Singer.....1398–1408
Mill Preset Screw-Down Controllers, Improvements in Rolling. Leitch, Schurr.....58–63
Mills, An X-Ray Thickness Gauge for Hot-Strip Rolling. Clapp, Pohl.....620–6
Mills, Electric Equipment for Cold Strip Reduction. Miller.....133–9; disc. 139
Mills, The Reversing Cycle of Modern Blooming. Montgomery, Sellers.....1508–13; disc. 1513
Mines, Causes and Effects of Stray Electric Currents in Coal. Harrison.....1759–61
Mines, Shipboard Degaussing Installations for Protection Against Magnetic. Michel..1270–5; disc. 1275
(Mining) Electric Equipment for Power Shovels and Draglines. Schwedes, Stoetzel.....1498–1506; disc. 1507
(Mining) Evolution of Ward-Leonard Control for Shovels and Draglines. Stevens.....1491–7
(Mining) Power Distribution and Utilization in a Large Iron Ore Beneficiation Plant. Gettelman..1726–32
(Mining) Trends in Electrification of American Steel Industry. Umansky.....784–95
Mining, Utilization of Electric Power in Open-Pit Copper. French, Speight.....956–66; disc. 966
Mobile Radio. Bailey.....923–31; disc. 932
Models, A Study of A-C Arc Behavior Near Current Zero by Means of Mathematical. Browne.....141–50; disc. 150

Models for the Solution of Cable Temperature Problems—II, Use of Reduced-Scale. Gemant, Stichter....28–33; disc. 34
Modern Blooming Mills, The Reversing Cycle of. Montgomery, Sellers.....1508–13; disc. 1513
Modern Trends in Hydraulic Turbine Design. Rheingans.....1075–80
Modernization and Faster Fault Clearing on Single-Phase Electrified Railroad, Circuit Breaker. Brown, Travers, Wood.....705–13; disc. 713
Modulation Receiver Design Trends, Frequency. Young.....1514–19
Motional Characteristics of Permanent-Magnet Movable-Coil Instrument Mechanisms, A Bridge Method for Determining the. Gilbert.....411–15
Motive Power on the Great Northern Railway Electrification, Comparative Operating Results of Steam, Diesel-Electric, and Electric. Gaynor.....231–4; disc. 234
Motive Power Operation in the Pacific Northwest, The Present Competitive Position of Coal, Residual Oil, Diesel Oil, and Electricity as Energy Sources for. Martin.....1664–9
Motor Design Information, A Method of Selecting Inherent Overheat Protectors Based Upon. Vaughan.....1023–9; disc. 1030
Motor Hunting, Oscillographic Study of Synchronous. Kurtz.....647–52
Motor, Origin of the Electric. Michalowicz..1288–92
Motors for Shipboard Use, Overload Protection of Silicone-Insulated. Grigg, Watkins.....1341–4; disc. 1344
Motors From Controlled Rectifiers, Operation of Large D-C. Schmidt, Smith.....679–83
Motors, or S. F. Test, The "Superimposed Frequency Test" for Induction. Romeria....952–3; disc. 953
Motors, The Liquid Rheostat for Speed Control of Wound Rotor Induction. McFarland, Alvarez.....603–09; disc. 609
Movable-Coil Instrument Mechanisms, A Bridge Method for Determining the Motional Characteristics of Permanent-Magnet. Gilbert.....411–15
Multijet Airplane, Starter-Generator Control System for a. Hart.....1316–18
Multivalve Condensing Steam Turbine-Generators, Speed Governing Design Considerations for. Barnett.....1557–61; disc. 1561

N

Naval Ordnance Laboratory Six-Trace Cathode-Ray Oscillograph, The. Edwards.....1220–23
Naval Shipboard Applications, Magnetic Amplifiers for. Buechler.....1241–5; disc. 1245

Tartrate in Place of Quartz, Crystal Filters Using Ethylene Diamine. Willis....552–6
Telegrams, Facsimile Transmission for Pickup and Delivery of. Ridings....1293–8
Telegraph Signal Analyzer, A. Erickson....380–4; disc. 384
Telegraph Systems, Push Button Switching in. Blanchard, Blanton....1733–40
Telemeter for Carrier-Current Channels, A Faster. Lynch, Thomas, Lunge....288–94; disc. 294
Telemeter, New Devices Derived From a Torque Balance. Burnham....307–10
Telemetering and Load Control, Characteristics of New Carrier-Current Equipment for. Beckwith....1649–52; disc. 1652
Telemetering and Load Control, System Operation Improved With Carrier. Walton, Lenner....1643–7; disc. 1647
Telemetering, Carrier Channels for. Talmage....1448–56; disc. 1456
Telemetering Circuits—Metallic and Carrier. Bostwick....1081–6; disc. 1086
Telemetering System, A Universal. Harris....1151–4; disc. 1154
Telephone and Television Systems, Progress in Coaxial. Abraham....1520–7
Telephone Cables, Recent Improvements in Loading Apparatus for. Hale, Quinlan, Ranges...385–92
Telephone Service in America, Radio for. Romnes....1060–7
Telephone Switching, Relay Preference Lockout Circuits in. Joel....1720–5; disc. 1725
Telephone Switching Systems, The "Director" for Automatic. Smith....611–19
Teletape Facsimile, Western Union. Pollard..511–15
Teletypewriter Systems of World War II, Military. Singer....1398–1408
Television Receiving Systems. Sinnett....1544–8
Television Systems, Progress in Coaxial Telephone and. Abraham....1520–7
Temperature, Aging Characteristics of Dry-Type Transformer Insulation at High. Stewart, Whitman....1600–06; disc. 1607
Temperature and Depth of Sea Water, An Instrument for Recording Continuously the Salinity. Jacobson....714–22
Temperature, Electrical Properties of Ceramics as Influenced by. Lindsay, Berberich....734–41; disc. 741
Temperature Problems—II, Use of Reduced-Scale Models for the Solutions of Cable. Gemant, Sticher....28–33; disc. 34
Temperatures Continuously with the Transformer Carrying Load, Measuring Transformer Winding. Lockie, Stein....1608–16; disc. 1616
Ten Years Performance of Lightning-Resistant Wood-Pole Transmission Lines. Schafer, Kuntz....934–40; disc. 940

Terminations for Microwaves, Attenuator Materials, Attenuators and. Teal, Rigterink, Frosch..419–28
"Terratex"—A Thin Flexible Inorganic Insulation. Walters.....123–7
Test" for Induction Motors, or S. F. Test, The "Superimposed Frequency. Romeira..952–3; disc. 953
Test of the Allgemeine Elektricitats Gesellschaft Free-Jet Air-Blast 220-Kv 2,500-Megavolt-Ampere Reclosing Circuit Breaker, Performance. Dovjikov, Diemond.....295–304; disc. 304
Test on Rapid Transit Division, Chicago Transit Authority, Three-Compartment Articulated Cars for. Otis.....416–18
Testing of Wire and Cable, Statistical Methods as Applied to the Manufacture and. Woolfson.....752–4; disc. 754
Tests Carried Out at the 500-Kv Experimental Station of Chevilly (France), Especially on Corona Behavior of Bundle Conductors, Results of. Cahen.....1118–25; disc. 1125
Tests for Development of 10,000,000 Kva 230-Kv Oil Circuit Breakers for Grand Coulee Power Plant, Field. Killgore, Clagett.....271–83; disc. 283
Tests, Relaying Difficulties Disclosed by Staged-Fault. Morgan, Evans.....73–82
Tests, Unusual Performance of Standard 230-Kv Impulse and Tank-Type Oil Circuit Breakers on Field. Rietz.....267–70; disc. 270
Textile Industry, Electrical Progress in the. Snyder.....863–70; disc. 870
Thermal Characteristics of a 120-Kv High-Pressure, Gas-Filled Cable Installation. Sanderson, Sticher, McGrath.....487–98; disc. 499
Thermionic Gas Tubes, Quadrature Operation of Filamentary. Holdaway.....205–08
Thickness Gauge for Cold-Rolled Strip Steel, X-Ray. Lundahl.....83–90
Thickness Gauge for Hot-Strip Rolling Mills, An X-Ray. Clapp, Pohl.....620–6
Thickness Indicator for Journal Bearings, Oil Film. Greenough.....589–95; disc. 595
Three-Compartment Articulated Cars for Test on Rapid Transit Division, Chicago Transit Authority. Otis.....416–18
Three-Phase Coaxial Buses Comprised of Square Tubular Conductors, Proximity Effect Factors for. Higgins, Messinger.....1538–9
Thyratron Tubes, A Method for the Measurement of the Ionization and Deionization Times of. Birnbaum.....209–14
Thyratrons, A New Line of. Coolidge..723–7; disc. 727
Time Control, Preliminary Consideration of System-Wide Load Divisions by Means of Accurate. Curtis, Pickslay.....1562–9; disc. 1569
Time Ratings of Diesel-Electric Locomotives, Short. Campbell, Woods.....1661–3
Torque Balance Telemeter, New Devices Derived From a. Burnham.....307–10
Torques in Turbine Generators Produced by Transmission-Line Reclosing, Transient Shaft. Batchelor, Whitehead, Williams.....159–64; disc. 164
Toxicity, Silicone Insulation in Submarines—. Walker, Shea.....1232–6
Traction Generator Comes of Age, The Locomotive. Lamborn.....767–71
Traffic on Steam Railroads, Handling Suburban. Sloman.....1670–4
Traffic, Power Costs and the Contribution of Existing Transmission Networks Towards Cost Reduction of Power for Electrification of Main Line Railroads. Evans.....596–8; disc. 599
Train Braking, A Unique Application of the Wheatstone Bridge to High-Speed. Hines.....360–2
(Transformer) Electrical Insulation Deterioration Treated as a Chemical Rate Phenomenon. Dakin.....113–18; disc. 118
(Transformer) Feeder Voltage Regulator Accuracy Standards. Birchard.....747–51; disc. 751
(Transformer) Feeder Voltage Regulator Application on Power Systems. Gosinski, Oberholtzer.....1458–61; disc. 1461
Transformer Impulse Failure Detection Methods, Experience with. Aicher.....1621–7; disc. 1627
Transformer Insulation at High Temperature, Aging Characteristics of Dry-Type. Stewart, Whitman.....1600–06; disc. 1607
(Transformer) "Terratex"—A Thin Flexible Inorganic Insulation. Walters.....123–7
Transformer Winding Temperatures Continuously With the Transformer Carrying Load, Measuring. Lockie, Stein.....1608–16; disc. 1616
Transformers Due to Lightning Currents in Low-Voltage Circuits, Voltage Stresses in Distribution. Beardsley, McMorris, Stewart.....1632–5; disc. 1635
Transformers, Influence of the Core Form Upon the Iron Losses of Transformers. Stein...95–103; disc. 103
Transformers, Instantaneous Bus-Differential Protection Using Bushing Current. Seeley, von Roeschlaub.....1709–18, disc. 1718
Transient Shaft Torques in Turbine Generators Produced by Transmission-Line Reclosing. Batchelor, Whitehead, Williams.....159–64; disc. 164
Transit Division, Chicago Transit Authority, Three-Compartment Articulated Cars for Test on Rapid. Otis.....416–18
(Transmission) A Large-Scale General-Purpose Electric Analog Computer. Harder, McCann.....664–73
(Transmission) A 10,000-Kva Series Capacitor Improves Voltage on 66-Kv Line Supplying Large Electric Furnace Load. Jones, Arthur, Stearns, Johnson.....345–51; disc. 351
(Transmission) An Experimental Investigation of the Electrical Performance of Bared Aluminum-to-Copper Connections. Bonwitt..1208–18; disc. 1218
(Transmission) Change of Frequency on the System of the Southern California Edison Company. Tice, Kroneberg, Johnson, Enefer, Tugby, Sidway.....809–25; disc. 825

Preface

The 1948 TRANSACTIONS (volume 67) of the American Institute of Electrical Engineers will be published in two parts.

Part I contains technical program papers and related discussions presented at general meetings and District meetings during the first half of the calendar year as follows:

1. Winter general meeting, Pittsburgh, Pa., January 26–30, 1948.*
2. Great Lakes District meeting, Des Moines, Iowa, April 1–3, 1948.
3. North Eastern District meeting, New Haven, Conn., April 28–30, 1948.
4. Summer general meeting, Mexico, D. F., Mexico, June 21–25, 1948.

[Only ten Summer general meeting papers are included in Part I. The remainder of the Summer General meeting papers will be included in Part II together with the approved papers and related discussions presented at the Pacific general meeting; the Middle Eastern District meeting; the Midwest general meeting; and the Southern District meeting.]

Full correlation of all material in this volume has been accomplished by means of the multientry index beginning on page 854. Reference to any of the several subject entries for a technical paper will lead directly to the paper and to any published discussion on that paper.

Statements and opinions given in papers and discussions published in TRANSACTIONS are the expressions of contributors for which the American Institute of Electrical Engineers assumes no responsibility.

Part II of Volume 67 is expected to be available for distribution during the spring of 1949.

* (47-237 "Present-Day Grounding Practices on Power Systems"—Third AIEE Report on System Grounding, was presented at both the Winter general meeting in Pittsburgh, and the Midwest general meeting held November 3–7, 1947. This paper was included in the 1947 bound volume of TRANSACTIONS.)

Preface

The 1948 TRANSACTIONS (volume 67) is published in two parts. The contents of Part I are listed on the preface page in Part I of the 1948 volume.

Part II contains technical program papers and related discussions presented at general and District meetings during the second half of the calendar year as follows:

1. Summer general meeting, Mexico, D. F., Mexico, June 21–25, 1948.*
2. Pacific general meeting, Spokane, Wash., August 24–27, 1948.
3. Middle Eastern District meeting, Washington, D. C., October 5–7, 1948.
4. Midwest general meeting, Milwaukee, Wis., October 18–22, 1948.
5. Southern District meeting, Birmingham, Ala., November 3–5, 1948.

* Ten Summer general meeting papers were published in Part I and the remainder are included in Part II.

Part I of volume 67 contained an index covering only the first half of the year. A complete index for 1948 (Parts I and II) is included in this volume beginning on page 1799. The Report of the Board of Directors, and the list of Officers and Committees for 1948–1949 are also included in Part II.

Statements and opinions given in papers and discussions published in TRANSACTIONS are the expressions of contributors for which the American Institute of Electrical Engineers assumes no responsibility.

Generator Stability at Low Excitation

E. L. MICHELSON

L. F. LISCHER
ASSOCIATE AIEE

Synopsis: The addition of static capacitors for power factor correction on the 4-kv distribution circuits of the Chicago, Ill., system has resulted in the operation of generators at power factors close to unity during light load periods. This introduces a problem of generator stability at low levels of excitation. It is the purpose of this paper to present the results of a study on the behavior of the generators on the Chicago system during these light load periods, and to show to what extent capacitors may be added to the system without resorting to capacitor switching. The paper shows that loss of generator field presents the most serious problem in the operation of generators during such light load periods. The results of this analytical study indicate that the generators on the Chicago system may be operated safely at high power factors.

IN THE CHICAGO interconnected system the problem of generator stability within the city has been relatively unimportant in the past due to the heavy interconnections between generators in the city. The schematic diagram of the Chicago system, Figure 1, shows the extent of this interconnection between generators in the city. All 66-kv lines consist of relatively short single-conductor cables rated at 60 or 100 megavolt-amperes, and in several instances two lines are operated in parallel. The 66-to-12-kv transformers are 60 or 100 megavolt-amperes, usually two being operated in parallel. The use of phase isolated construction on the 12- and 66-kv busses throughout the city has practically eliminated the possibility of phase-to-phase faults on the major busses on the system, and phase to ground fault currents are limited by neutral impedance. As a result of the heavy interconnections and infrequency of major faults, the question of transient stability between machines in the city has not presented a serious problem.

During the past few years, static capacitors have been installed on the 4-kv distribution circuits for power factor correction. Many studies have been made which show the economic desirability of using capacitors to provide reactive power for the load instead of supplying this reactive power by other means.[1] At the end of 1946 there were approximately 100 megavolt-amperes of static capacitors connected on the 4-kv system in Chicago, and it is expected that within the next few years an additional 100 megavolt-amperes will be connected. The effect of these capacitors, coupled with the capacitance effect of the very large amount of 132 kv, 66 kv, and lower voltage cables, has resulted in the reactive load on the generators being reduced materially. Recently generator power factor has averaged as high as 0.98 lagging under light load conditions. As a result the generators have been operating at reduced levels of excitation, thus introducing the problem of generator stability at low excitation.

The problem is aggravated by the difficulty in maintaining equitable reactive distribution among the generators. To maintain satisfactory service to customers, it is necessary to control the bus voltage within rather narrow limits. This is accomplished by control of generator excitation and by adjusting taps on the tap-changers of the 66-to-12-kv transformers. Because these taps are in steps of 2.5 per cent and the impedance between generating stations is low, each tap change results in an appreciable shift of reactive power. This creates for the load dispatcher a rather difficult and lengthy task of distributing the available reactive load among the generators at a time when he is already occupied with various switching operations for maintenance purposes. Operating practice on the Chicago system has, in the past, been based on operating generators only at lagging power factors and preferably at power factors no higher than 0.95 to 0.98.

Various corrective measures have been considered to maintain lagging power factor on the generators with the increased number of capacitors on the system.[2] One solution to the problem is to disconnect the capacitors under light load conditions by clock control or current control. However, in the case of the Chicago system, the 4-kv circuits are relatively short and the switching of capacitors is not required to meet voltage standards as is the case on systems with long circuits; therefore, the major cost of capacitor switching (installation and maintenance) must be charged to the regulation of generator power factor. Also, this type of equipment on the overhead system is inherently undesirable in the urban area due to space limitations, general appearance, and difficulty of maintaining such equipment on an overhead system. The capacitors with switches can be installed in substations, but this reduces materially the possible savings. Another method for regulating generator power factor is to switch the high-voltage cables as required. However, this is an undesirable practice due to the weakening of the transmission system, the hazards involved in switching high-voltage cables, and the dispatching time required to perform the operations. Another solution which was considered was the installation of shunt reactors at generating stations, but this proved to be uneconomical. One method of regulation which has been practiced is to run synchronous condensers underexcited so that instead of gener-

Paper 48-2, recommended by the AIEE power generation committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted April 7, 1947; made available for printing November 13, 1947.

E. L. MICHELSON and L. F. LISCHER are both with the system planning division, engineering department, Commonwealth Edison Company, Chicago, Ill.

The authors wish to acknowledge the help of S. B. Crary (F '45) and C. Concordia (M '37) of the General Electric Company, Schenectady, N. Y. in connection with the methods of analysis used in this study, and D. D. Higgins (M '27) and E. Wild (M '36) of the Commonwealth Edison Company, Chicago, Ill., in connection with the various operating problems covered by the paper.

ating reactive power they will take a maximum amount of reactive kilovolt-amperes from the system.

It can be seen that it is desirable to install the capacitors without switching to the greatest extent consistent with safe operation of the generating system. It is the purpose of this paper to present the results of a study which has been made for the Chicago system to determine the behavior of the generators during light load periods and to establish thereby to what extent the capacitors could be installed without automatic switching. It should be appreciated that many of the factors entering into such a study are not known with a high degree of accuracy, but it is believed that the results of the study described in this paper are sufficiently accurate to draw practical conclusions. The a-c network analyzer was used in some parts of the study, and information from actual cases of system trouble have aided greatly in analyzing the general problem and arriving at practical conclusions.

Calculation of Pull-Out Limits

As the first step in the study, calculations were made to determine the pull-out limits of a typical generator in Chicago. The problem first was considered as one of steady-state stability—to determine the pull-out limits of a generator with constant field current.[3] It was assumed that the generator is feeding into an infinite system, the rotating capacity on the solidly connected portion of the system alone at this time being approximately 800 megawatts. The machine, which was first considered, is the latest to be installed in Chicago; it has a rating of 147 megawatts at 0.85 power factor and has a short circuit ratio of 0.88. This ratio is typical of most of the machines in the city, although there are a few cases of rather extreme departure from this normal value ranging from 0.6 to 1.4. A preliminary study was made as to whether a simplified method of taking saturation into account would be adequate for the problem. This comparison is outlined in Appendix I, and, as indicated there, it was found that the use of $1/SCR$ (short-circuit ratio) as the machine impedance gives reliable results in the range of values with which this problem was concerned.

The results of the pull-out calculations are shown in Figure 2. A study of this figure indicates that there is considerable margin under practically all power factor conditions. The amount of load, as will be shown later, that any one generator will be forced to pick up under various conditions is relatively small, and the

number of degrees that any one machine can swing ahead of the remainder is limited because of the solid interconnections between machines. These factors tend to reduce the amount of margin required for stable operation, and it is estimated that a margin of 15 per cent would be sufficient for safe operation. These curves indicate operation at leading power factors to be feasible although they demonstrate that the rate of reduction of pull-out limits in the range of power factor from 0.95 lagging to 0.95 leading is material.

Effect of Fault Conditions

The curves of Figure 2 were calculated on the basis of steady-state system conditions and terminal voltage being maintained at the normal value. However, the criterion for safe operation must be based on maintaining stable operation under various fault conditions. These fault conditions include system short circuits, sudden loss of generating capacity, and sudden opening of transmission lines; loss of field is considered later on and is treated as a special problem. A review of the transient problem involved in analysis of the fault condition indicated that the effect of the initial power factor at which the machine was operating would have little effect on the transient condition. In other words, whether a machine was operating at 0.95 lag or 0.95 lead, the ac-

Figure 4. Final system voltage after loss of 120-megawatt generation during light load period as a function of initial generator power factor

tion under a transient condition would be approximately the same. The air-gap flux is not greatly affected by the power factor of operation within the limits under consideration. Also, with the faults being cleared within a reasonable length of time, 0.5 second or less, there is not very much decay of flux within the machine. It appeared, therefore, that analysis of these fault conditions could be made on the basis of considering the steady-state condition of the system after the fault was cleared and the load has been redistributed on the system.

A review of system conditions indicated that the worst case of loss of generation to be analyzed, was the loss of a 150-megawatt unit with the load being picked up by the remaining machines in Chicago and the various stations outside feeding in through high-voltage lines. From a consideration of system capacity and from experience during various actual cases of system trouble, it was assumed that the loss of capacity within the city would result in about 25 per cent of the power being picked up by machines within the city. It was also assumed that the reactive power deficit caused by the loss of the generator actually more important than the megawatt loss from the voltage viewpoint would be made up entirely by the machines within the city.

An important factor in determining the characteristics of the system for sudden loss of generating capacity is the variation of load with changes in system voltage. Various system tests have been performed in Chicago which have indicated the relationship between voltage and load for the combined load in the city. The results of these tests are shown in Figure 3. With the assumption and data outlined, it was possible to determine the change in system voltage resulting from the loss of a large generator, Appendix II. The results of this study are shown in Figure 4. From this curve it can be seen that even the loss of the largest generator in the city does not cause a large change in system voltage and therefore the pull-out limits of Figure 2 would not be changed appreciably. Since the pull-out limit is directly proportional to the terminal voltage, Appendix I, the limit for any value of terminal voltage other than 1.0 may still be obtained from the curves of Figure 2. An interesting point which is shown by Figure 4 is that the reduction in system voltage is less for higher power factors of operation, and if the machines are operating at an appreciable leading power factor, there will actually be an increase in system voltage when a machine is lost This tends to improve the stability of the system and offsets to some degree the reduction in stability limits resulting from low excitation.

In arriving at a conclusion for the margin required in the operation of generators in terms of the curves of Figure 2, it is also necessary to consider the governor characteristics of the individual machines and the amount the entire system frequency is likely to drop under abnormal system conditions. Governors on the Chicago system have average characteristic slopes varying between 4 and 25 per cent. In the case of the 4 per cent governor this means that for a decrease in speed of 4 per cent the machine will pick up 100 per cent load. For the case of 120-megawatt loss of generation described previously, the system frequency will drop approximately 0.1 cycle, 0.17 per cent, as shown by actual cases of trouble. It can then be seen that a 4 per cent governor with a drop in frequency of 0.5 per cent will attempt to force the machine to pick up 12.5 per cent load, 12.5 per cent of its megawatt rating. Thus a margin of 20

per cent for a machine with a 4 per cent governor would appear to be ample, and for the great majority of turbines with less sensitive governors, 12 per cent, a 15 per cent margin is adequate.

Loss of Field

Another type of trouble to which power systems are subjected is the partial or complete loss of field on generators. In Chicago, over a period of years, there have been several such cases of trouble, although none have resulted in voltage instability of the system.[4] Such cases of trouble are caused by the incorrect opening of the field circuit breaker, connectors between field poles opening, collector ring leads burning off, exciter field resistors opening, and so forth. In order to determine the effect of change in excitation on the degree of trouble caused by loss of field, a study was made to determine the effect of loss of field of the largest machine in Chicago under both heavy and light load system conditions. For the purpose of the study, the principal effect to be determined was the reduction in the steady-state voltage of the system and no transient study was made. The method of obtaining these values is discussed in Appendix III, and the results of the calculations for the light-load system conditions are shown in Figure 5. This figure shows the relationship between the slip frequency at which the machine operates and the power output, reactive input, and system voltage. The slip frequency at which the machine will actually operate depends on the initial megawatt loading of the machine and its governor charac-

Figure 7. Determination of saturation factor k and short-circuit ratio from the generator no-load saturation and short-circuit characteristic curves

Figure 8. Saturation factor k as a function of e_l based on no-load saturation curve

teristic. However, if the machine is operating at an appreciable load, above 0.50 for the conditions indicated, the terminal conditions on the machine will fall on the flat portion of the curves, and the result will be largely independent of the exact slip frequency. From this figure it can be seen that the machine will take well over full-load current as the reactive input to the machine or approximately 200 reactive megavolt-amperes for the machine involved. With this much reactive power taken by the machine, the system voltage is reduced to approximately 0.60 for the light load system condition. The comparable figures for the heavy load system condition are an input of approximately 300 reactive megavolt-amperes and a system voltage of about 0.80.

From the standpoint of system stability, the important effect of loss of field is the reduction in system voltage, which in turn will reduce the pull-out limits of the remaining machines on the system. Table I shows the reduced value of pull-out limits for the typical remaining machines with the system voltage reduced to 0.60. This table indicates that machines carrying loads of 0.75 of their rating or above, will be operating at or near their pull-out limits. On the other hand, these machines will be near their stability limit even with the lagging power factors which have in the past been considered safe operating points. It therefore appears that the magnitude of the problem created by loss of field is not greatly affected by the number of static capacitors which may be added to the system.

Conclusions

This paper describes the results of a study made for the Chicago system to determine the stability of the generators during light load system conditions, and to establish therefrom to what extent unswitched static capacitors could be added to the distribution system. The conclusions which have been reached from this analytical study of the Chicago system are as follows

1. An analysis of the pull-out curves for a typical generator as shown in Figure 2 shows that with constant-terminal voltage and constant-field current, generators can operate in the leading power-factor zone and still have ample margin to pick up an increment of load greater than that which the machines will be required to pick up under abnormal operating conditions.

2. Within the limited range of generator power factor considered in this paper, the initial power factor of the machines has very little effect on the transient stability of the system.

3. The loss of power supply due to the loss of the largest unit will not create a sufficient reduction in voltage and change in operating conditions to cause instability, even with power factors in the leading zone.

From these facts it may be concluded that unswitched capacitors may be added to the 4-kv distribution system until a generator power factor of 1.0 is reached.

Nomenclature and Symbols

e_t = Generator terminal voltage (assuming the generator reactor to be part of the generator); also used as system voltage unless otherwise specified
e_e = System voltage
e_i = Internal generator voltage—voltage behind x_d, $1/SCR$, and so forth, as specified
e_l = Voltage behind generator leakage reactance, x_l
i_t = Total armature current
x_d = Generator direct axis synchronous reactance, unsaturated
x_d' = Generator direct axis transient reactance
x_d'' = Generator direct axis subtransient reactance
x_l = Armature leakage reactance
x_{RR} = Generator reactor reactance
x_c = External reactance
x_g = Generator reactance, including reactor, based on x_d, $1/SCR$, and so forth, as specified
x_{rd} = Rotor direct axis synchronous reactance
x_{rq} = Rotor quadrature axis synchronous reactance
r_{rd} = Rotor direct axis resistance
r_{rq} = Rotor quadrature axis resistance
x_r = Equivalent rotor reactance
r_r = Equivalent rotor resistance

(b). Based on $x_g = \frac{1}{SCR}$

(c). Based on $x_g = x_l + \frac{x_d - x_l}{k}$

k = Saturation factor as obtained from generator no-load saturation curve
SCR = generator short-circuit ratio

Appendix I

Determination of Generator Pull-Out Curves

It is well known that the effect of saturation on the pull-out characteristics of a generator is appreciable.[5-8] Because of the

Figure 11. Equivalent circuit for the case of generator connected to a noninfinite system

large number of generators in Chicago and a correspondingly wide range of generator constants (such as x_d, short circuit ratio, and so forth), three series of calculations were made for one generator with fairly typical constants to determine how the saturation effect may most easily be taken into account with reasonable accuracy. The calculations of series 1 neglect saturation; those of series 2 assume a constant value of saturation; and those of series 3 assume a variable value of saturation. The following assumptions are common to all three series of calculations:

1. Terminal voltage remains constant; $e_t = 1.0$
2. Field excitation remains constant at initial operating point (no automatic voltage regulation).
3. Generator losses (resistance) were neglected so that the equation for maximum generator power output becomes

$$P_{max} = \frac{e_l e_t}{x_g}$$

4. Generator data
Rating: 173 megavolt amperes at 0.85 power factor (2-winding cylindrical rotor)
147 megawatts = 1.0 load
12.6 kv = 1.0 voltage
x_d (unsaturated) = 1.24, per unit on 173 megavolt amperes
x_{Rx} = 0.04, per unit on 173 megavolt amperes
$x_l = x_d'' - .03 = 0.08$, per unit on 173 megavolt amperes
Short circuit ratio = 0.88 at 12.6 kv

$$\frac{1}{\text{Short circuit ratio}} = 1.17 \text{ (including reactor), per unit on 173 megavolt amperes}$$

Series 1. Based on $x_g = x_d$ (unsaturated). See Figure 6*a* for the equivalent circuit used. Neglecting saturation will, of course, give pessimistic results and these were used as a guide. See Figure 10, curve *a*.

Series 2. Based on $x_g = \frac{1}{SCR}$. This takes saturation into account but assumes it to be constant for all ranges of generator loading and power factor. See Figure 6*b* for the equivalent circuit used. Values of pull-out limits obtained this way, in the range of 0.9 power factor lag to 0.9 power factor lead, are from 3 to 11 per cent higher, depending on power factor and loading, than those in Series 1. See Figure 10, curve *b*.

Series 3. Based on

$$x_g = x_l + \frac{x_d - x_l}{k}$$

maximum power then becomes:

$$P_{max} = \frac{(e_l/k)(e_t)}{x_l + \frac{x_d - x_l}{k}}$$

This takes saturation into account fairly accurately (as it varies with generator loading and power factor right up to the pull-out point). The saturation factor k was obtained from the no-load saturation curve as is shown in Figure 7. It should, strictly

Figure 12. System equivalents for loss of unit during light load period

expressed in per unit on 920-megavolt-ampere base
(a). Condition before loss of unit
(b). Condition after loss of unit but before adjusting megawatts and reactive megavolt-amperes for new e_t

speaking, be obtained from the load-saturation curves, but normally these are not available. Values of k may then be plotted against varying values of e_l. Figure 8 shows how k varies with e_l. The calculations for pull-out limits can be made by using the graphic method or the a-c network analyzer, but either way it is a trial and error method. Figure 6*c* shows the equivalent circuit used and Figure 9 shows the vector diagram for one condition of initial loading. The pull-out limits as obtained this way, Figure 10*c*, agree very closely with those in Series 2. At power factor = 1.0 the values are identical; at power factor = 0.9 lag the values are 1 per cent higher; at power factor = 0.9 lead the values are 2 per cent lower—this is to be expected because there is less saturation at leading power factor.
Rewriting

$$P_{max} = \frac{(e_l/k)(e_t)}{x_l + \frac{x_d - x_l}{k}}$$

as

$$P_{max} = \frac{e_l e_t}{x_d - x_l + k x_l}$$

the effect of k becomes more readily discernible. For example: for initial load = 1.0 at 0.9 power factor lag, k will be 1.12; at the pull-out point i_l will lead e_t by approximately 30 degrees and k then will be 1.05. The change in the value of k, after determining the initial e_l, has practically no effect on P_{max}, since x_l is approximately equal to $0.1\,(x_d - x_l)$.

Results. In Figure 10 are plotted the pull-out values of the generator for 1.0 and 0.5 initial load as obtained by the three series of calculations. It can be seen that, for the accuracy required in most practical applications, using $x_g = 1/SCR$ is adequate in the range of generator power factor = 0.9 lag to 0.9 lead.

Effect of external reactance. If it may not be assumed that the generator under consideration feeds directly into an infinite bus, then the effect of external reactance must be taken into account. The x_e may be handled in similar manner as the x_{Rx}. Carrying through one series of calculations when $x_e = 0.08$, then P_{max} as shown in Figure 2 is reduced by approximately 6 per cent. If the amount of rotating capacity on the system is not great enough to permit the assumption of an infinite system, then the equivalent circuit as shown in Figure 11 may be used as an alternative.

Table I. Reduction in Pull-Out Limits Caused by Reduced Terminal Voltage

Initial Gen. P.F.	Initial Gen. Load	Pull-Out Limit $e_t = 1.0$	Pull-Out Limit $e_t = 0.60$
0.98 lag	1.0	1.55	0.93
	0.75	1.37	0.82
	0.50	1.20	0.72
	0.25	1.08	0.65
1.0	1.0	1.41	0.85
	0.75	1.26	0.75
	0.50	1.12	0.67

	0.50	1.03	0.62
	0.25	1.00	0.60

Appendix II

Determination of System Voltage After Loss of a Large Unit During Light Load Period

In determining the system voltage after loss of a large unit, the first assumption that

must be made is the amount of load the remaining units must pick up. In the case under consideration the remaining generators in the city would pick up 20 to 25 per cent of the megawatt generation lost, as shown by actual cases of trouble; the remainder of the load would then be picked up by generators outside the city feeding in through high-voltage lines. It was further assumed that the generators outside of the city would not pick up any of the reactive generation lost because these generators would not feel appreciably the drop in voltage.

It is of considerable help if the load-voltage characteristic of the system load is known.[8] Figure 3 shows the load-voltage characteristic of the Chicago system load as obtained from actual system tests. In the calculation for determining system voltage after loss of a unit, the drop in load due to the drop in voltage was taken into account. Because the load-voltage curves are about four years old, they actually do not include the effect of 4-kv capacitors; hence the capacitors have been lumped in with the cable charging effect, and this too was corrected for change in voltage. No automatic voltage regulation was assumed.

Figure 12 shows the equivalent circuits used in this analysis with figures for the condition of generator power factor equals 0.90 lag.

Appendix III

Determination of Terminal Conditions for Loss of Generator Field

To simplify and reduce the problem to its basic elements, the following assumptions were made:

1. The problem was solved for the steady-state condition, assuming that the transient condition would cause no undue distress to the system. The rate of decrease of system voltage will be comparatively slow and the worst system condition will exist when the machine has reached its ultimate value of slip.[9] The amount of this slip will depend on the amount of initial load on the generator, and the turbine governor characteristic.

2. The loss of field was taken to be a complete loss, such as that obtained by opening the field switch, so that the generator field discharge resistor is connected across the generator field.

3. Rotor losses were neglected. These were determined to be approximately 0.04 at 0.045 slip, most of this loss being in the iron. Saturation was neglected.

4. All of the remaining generators on the system were combined into one equivalent generator. The equivalent reactance was obtained from values of short-circuit megavolt-amperes using generator synchronous reactance.

5. The load was permitted to drop as the voltage decreased. Because the decrease in voltage was so great on loss of field and the load-voltage characteristic curves do not go below 0.92 voltage, the best compromise was thought to be that of treating the load as a constant impedance load.[11] This is somewhat optimistic, as a check shows that by assuming constant impedance, the terminal voltage in one instance is 0.80, whereas an adjusted value of terminal voltage, based on extrapolation of load-voltage curves, shows that a_t might more nearly be between 0.75 and 0.77. However, because so little is known of composite load-voltage characteristics at low voltages, 0.60 to 0.90, it was felt that using constant impedance load and viewing the results as being optimistic by perhaps 5 per cent was a reasonable solution.

6. Characteristics of the generator which was assumed to lose its field:

176.5 megavolt-amperes, cylindrical rotor
150 megawatts, 0.85 power factor

$x_d = 1.27$, on 176.5 megavolt amperes
$x_l = 0.10$, on 176.5 megavolt amperes
$x_{Rx} = 0.09$, on 176.5 megavolt amperes
$SCR = 0.85$
Speed = 1,800 rpm

7. No automatic voltage regulation was assumed.

Figure 14. Equivalent circuit for combining direct and quadrature axis impedance into equivalent x_r and $-r_r$

Figure 13. Variation of equivalent $-r_r$ and x_r with slip; these are average values over one slip cycle

Curves are for typical large solid-rotor turbogenerator

The variation of rotor x_r and $-r_r$ with slip of the unit under consideration must be known. Figure 13 shows such curves for a typical large solid-rotor turbogenerator. This information is usually obtained in terms of rotor x_{rd}, x_{rq}, $-r_{rd}$, and $-r_{rq}$; the in-phase and quadrature components may be combined into equivalent x_r and $-r_r$ by using an equivalent circuit such as is shown in Figure 14. Note that equivalent system transient reactance is used in this combination. It is also to be noted that these values of x_r and $-r_r$ are the average values over one slip cycle assuming constant slip.

The solution then for the terminal voltage, power output, and reactive input of the generator which has lost its field is most readily accomplished by using the a-c network analyzer; the generator may be represented by two reactances and a power-source in series, the power source being used to

Figure 15. Equivalent circuit for determining terminal conditions for loss of generator field

obtain $-r$ by inserting a series in-phase voltage of such magnitude that $e/i = -r$. The remainder of the system is set up by equivalents as is shown in Figure 15.

Discussion

T. W. Schroeder (The United Light and Railways Service Company, Davenport, Iowa): The question of generator stability when operating at high power factors during light system load is one which is brought up frequently in connection with the application of capacitors to power systems. The authors not only show that for the Chicago system the operation of generators at high lagging or even leading power factors creates no light load stability problem, a conclusion previously reasoned to be generally true,[1] but they also indicate high power factor operation practically does not aggravate the problem of loss of a machine field.

A very important factor in the light load stability problem, ably pointed out in the paper by Michelson and Lischer, is that in case of a sudden system load increase at light load, all machines on the system initially share the load increase as determined by their governor characteristics, so that no single machine is required to suddenly carry a large block of load, and a moderate stability margin is all that is needed. The only possibility of a problem is created if an operator, in loading a previously lightly loaded machine in redistributing load following a load increase, should fail to increase excitation of that machine at the same time. Even this problem is obviated if the machine excitation is under regulator rather than hand control.

In the calculations made by the authors to produce the data shown in Figure 2 of the paper, it is probably quite satisfactory to assume as they did that the machine operates against an infinite bus (use generator circuit impedance only and fixed terminal voltage regardless of load.)

To obtain an idea of the stability limits for various initial loads and power factors with a machine operating against a system of limited capacity, Figure 1 of this discussion was prepared using the method outlined in Appendix I of the paper. The conditions assumed were those which it is expected may obtain at light load on the United Light interconnected system after its several systems are in interconnected operation.[2] These conditions are

All units on one of the systems down except one 35-megawatt 0.8-power-factor. Balance of load carried by remote systems over 161-kv transmission line.

Other data:

Generator rating 43,750 kva, 0.8 power factor, 3,600 rpm
35,000 kw = 1.0 load
Short-circuit ratio = 0.9
X_d (external system reactance) = 29.3 per cent on 43,750-kva base

The results shown on Figure 1 of this discussion are probably not as accurate as those of Figure 2 of the paper, because the introduction of external system reactance into the calculation method results in a machine terminal voltage which varies with load on the generator being considered; the calculated terminal voltage at pull-out for the various power limits indicated on Figure 1 being as low as approximately 80 per cent of normal. If there is a good share of load on the same bus with the generator, this would lead to the conclusion that such load would be considerably reduced at pull-out; however, actually, with local load and maximum angular separation between machine and system, more of the local load will be supplied by the machine with the result that the load voltage will be held up.

Figure 1 in general indicates minimum stability margins of about 25 per cent, which in light of the previous discussion shows that high generator operating power factors are permissible even on systems of limited interplant capacity.

C. G. Adams (General Electric Company, Schenectady, N. Y.): It is pleasing to see that a practical system problem has been thoroughly analyzed by the authors resulting in justification of generator operation at low excitation where it is economically advantageous and simplifies operating procedures. It is noteworthy that correction to unity power factor at the generating station is allowable under manual control of excitation without substantially increasing the chance of system instability during a severe system disturbance caused by loss of field on a large machine. Automatic control of excitation and the use of out-of-step and loss-of-field relaying would serve to localize and quickly eliminate the system voltage disturbance.

Since the use of voltage regulators has not been mentioned, it would be interesting to know how their application would have affected the amount of unswitched capacitors that could have reasonably been applied in the distribution area of the system. This might result in generator operation at appreciable leading power factors at light load. Further conclusions that the authors may have reached based on the use of modern excitation systems would be most interesting.

W. H. Osterle (West Penn Power Company, Pittsburgh, Pa.): The West Penn Power Company has been concerned with high power factor on its generators for the same reason that actuated the study presented in this paper, namely the addition of static capacitors. Our load is naturally at high power factor at the generator terminals, the reactive requirements being such that a power factor of near 95 per cent is obtained throughout the 168 hours in the week. In order to carry the peak load nearly all reserve steam in the turbine is converted to kilowatts with only the reactive necessary for voltage. Static capacitors are installed at attended substations to hold up the system voltage on peak and are switched off if voltage becomes excessive under light loads.

A static stability study was made somewhat similar to that presented in this paper without arriving, however, at definite conclusions. Factors other than pull-out limits seemed to confuse the issue. It is with a great deal of pleasure therefore that we welcome this paper and others on the subject, as they should assist in arriving at sound operating procedure. We would like to ask the authors their opinion of our method and what led them to disregard some of the factors we considered.

Our method differs, first, in the determination of E_f or generator internal voltage. The authors assume a constant terminal voltage and calculate E_f by using various values of X_d. We obtained the E_f from the generator no-load and short-circuit saturation curve by determining the field excitation necessary to produce a given generator loading power factor, and terminal voltage then read E_f on the air gap line. This we say is the generator internal voltage necessary to give the proper value of E_t, allowing for armature reaction and generator reactance drop.

Our second difference is in the voltage we hold constant. The authors have assumed the terminal voltage constant, whereas we have considered an infinite bus voltage held constant. The infinite bus in our case was the 132 kv-bus at Springdale (Pa.) since the Springdale generators were being studied. This bus is supplied by five of the seven generators at Springdale through their own step-up transformer banks, and also by the entire interconnection through seven 132-kv lines.

Our third difference is in the external impedance used. The authors used no external impedance. We used an equivalent X_e to our infinite bus by paralleling all contributions of fault current to a 3-phase 132-kv bus fault. Our system is set up on our own d-c board with all power sources behind

subtransient reactance. A fault was placed on the 132-kv Springdale bus and each contribution reduced to equivalent reactance on a common base. These branches were then increased by the difference between the generator transient and sub-transient reactance and all paths paralleled. This gave an equivalent system reactance to generator internals behind transient reactance viewed from the 132-kv bus. This value, added to the generator X_d in question plus the step-up transformer reactance, gave the X_{total}.

In all of our calculations we used X_d unsaturated as we felt that at the point of pull-out the terminal voltage will be low enough to cause the generator to operate on the unsaturated portion of the saturation curve. Our calculations indicate a pull-out for most of our generators at unity power factor in excess of 1.15 when operating at full load. However, our full load is more nearly the turbine rating than the authors'. Assume a turbine rating equal to the megavolt-amperes of the machine—then the authors' generator would have a turbine of 1.177 per unit yet the calculated pull-out is in excess of 1.2 from 95 per cent power factor lead in the lagging direction. Does this mean that it would be impossible to reach a state of static instability in this region?

With so many generators in an interconnected system the incremental load picked up by each for the loss of a large block of power (generator or tie line) is rather small, depending upon the governor droop. Generators with large droop will pick up very little. The authors say only 25 per cent of the loss of a 150-megawatt unit will be picked up in the Chicago system. Furthermore, West Penn Power Company and many other utilities have voltage regulators on their generators which again help during system disturbance. Do not these factors minimize the case for static instability?

The authors' loss of field discussion is certainly extremely interesting and points up a condition that requires study. However, there are a few factors on which we are not clear. Do the conclusions pertain only to those machines on the same bus as the machine that loses field? Would the loss of the field of a generator at one generating station affect the generator at another station? Does the 60 per cent voltage refer only to the generator bus at the station involved or to the system voltage?

The authors have done a splendid job in presenting this rather technical subject of static stability and should do much to dispel doubt regarding the feasibility of operating generators at low excitation.

J. B. Ward (Purdue University, Lafayette, Ind.): This paper presents an interesting and useful analysis of limitations on generator operation at low excitation and a particularly interesting treatment of the loss of field on a large unit. From the standpoint of application to other systems a certain aspect of the method of analysis may warrant further clarification. In calculating the pull-out limits of a particular machine the authors assume that the machine in question is connected to an infinite bus. Then, in studying the effects of a generator outage or of loss of field, the system is represented as a noninfinite equivalent machine, and the curves of Figure 2 in the paper, for a generator connected to an infinite bus, are modified by adjusting the pull-out limits in proportion to the terminal voltage variation of the actual system. It seems to the writer that justification of this as a general procedure is not clear.

Figure 11 of the paper shows a suggested equivalent circuit for a non-infinite system, however, details on handling this case are not given. It may be of interest to compare the method of the paper with an alternative method in which the system is treated consistently as a noninfinite equivalent machine in a circuit similar to Figure 11. The method of approach described herein is presented for the purpose of illustrating, in a somewhat different manner, the effects of a generator outage on the pull-out limits of a particular machine.

Figure 2. Equivalent circuit

$X_1 = \frac{1}{SCR} + X_R = 0.68$, per unit on 100 megavolt-amperes

$X_2 = 0.1$, per unit on 100 megavolt-amperes (assumed)

$e_t = 1.0$ per unit (initial value)

Load = 314 megawatts and 152 reactive megavolt-amperes (lagging)

$Z_L = 0.258 + j0.125$, per unit on 100 megavolt-amperes

e_1 and e_2 calculated for each initial loading

The value of equivalent system reactance of Figure 15 is not given, but data of the paper indicate that this reactance is in the order of 0.1 to 0.13 per unit on 100 megavolt-amperes. A value of 0.1 is used here. In Figure 2 of this discussion, the 147-megawatt unit is to be tested for pull-out limits at various initial loadings, the remaining generating capacity is lumped into an equivalent machine, and Z_L is composed of the combined system load and static capacitors. This load is treated as a constant impedance.

The pull-out power of the 147-megawatt unit may be obtained by the familiar equation

$$\text{Max } P_1 = \frac{e_1^2}{Z_{11}} \sin \alpha_{11} + \frac{e_1 e_2}{Z_{12}} \qquad (1)$$

where

Z_{11} is the magnitude of the driving point impedance viewed from e_1

Z_{12} is the magnitude of the transfer impedance from e_1 to e_2

$\alpha_{11} = 90$ degrees $- \theta_{11}$ (θ_{11} is the impedance angle of Z_{11}).

The driving point impedance is calculated by paralleling the load impedance with x_2 and adding the result to x_1. The transfer impedance is obtained by making a wye-delta transformation. Table I of this discussion compares the results obtained by this method with data from Figure 2 of the paper for an initial loading on the 147-megawatt unit of 0.5 per unit.

In a metropolitan system with small equivalent system reactance and large load the solution might be simplified, without introducing large errors, by making two additional approximations

1. Neglect the first term of equation 1 since under the conditions specified α_{11} will generally be very small.

2. In computing the transfer impedance, neglect the load resistance and use for Z_L a reactance corresponding to the load reactive at the specified initial terminal voltage. This simplifies the wye-delta transformation.

The assumption of constant impedance load does not seem to be too serious, at least for the range of voltage variation included in Figure 3 of the paper. Check calculations were made at a terminal voltage of 0.92 per unit by modifying the load impedance in Figure 2 of this discussion to conform with the load characteristics shown in the paper. In these calculations the capacitors were separated and not modified since they conform to the constant impedance assumption. The effect of including load characteristics is to decrease the transfer impedance and increase the pull-out power approximately 1 per cent over that listed in Table I of this discussion, referring to the values obtained by the present method.

If the 147-megawatt unit is called upon to pick up load as a result of the loss of a large unit on the system, the internal voltage e_1 would remain the same, e_2 would not be appreciably affected, and both Z_{11} and Z_{12} would increase slightly due to the increase in equivalent system reactance. In considering the problem from this viewpoint it is difficult to reconcile the statement made in the paper, referring to Figure 4, that if the machine which is lost were operating at leading power factor, the pull-out limit would increase with the resulting rise in terminal voltage.

Applying the equivalent circuit of Figure 2 of this discussion to the calculation of the pull-out limit following the loss of field on one of the large units, assume that one of the machines included in the system equivalent suffers the loss of its field, and that it is desired to determine the pull-out limits of the 147-megawatt unit at various initial loadings. If the machine without field excitation imposes a reactive load on the system of 200 reactive-megavolt-amperes and reduces the terminal voltage to 0.65 per unit as shown in Figure 5, this may be represented in Figure 2 of this discussion by a reactance connected in parallel with Z_L and adjusted to produce a load of 200 reactive-megavolt-amperes at the predicted voltage. Treating the original load Z_L as a constant impedance, this parallel combination forms a new load which in turn modifies the driving point and transfer impedances. Also the equivalent system reactance increases as a result of the separation of the unit without field excitation. Calculations show that for an initial loading of 0.5 per unit on 147-megawatts at unity power factor this method gives a pull-out limit of 62 per cent of that shown in Figure 2 in the paper.

The numerical results compare favorably for this particular system. However, in terms of equation 1, of this discussion, the pull-out power is not proportional to the terminal voltage following an outage, assuming constant excitation voltages as established before the outage. This might be of importance in applying the method of the paper to a different system.

E. L. Michelson and **L. F. Lischer:** The discussers in their comments have added much that is of value and is useful in the analysis of this problem as applied to other systems.

In regards to generator pull-out calculations, the method mentioned by Osterle of determining the generator internal voltage for a given load and power factor from the saturation curves, starting with the known value of field current, does not differ essentially from the method of using $x_g = 1/\text{short-circuit ratio}$. In either case, saturation is taken into account. In one, by using values of field current and the saturation curves; in the other, by using a modified synchronous reactance—1/short-circuit ratio. It may be of interest that values of field current as obtained by calculation using $x_g = 1/\text{short-circuit ratio}$ agree very closely with actual readings of field current for different generator loadings in the region of 0.90-lag to 0.98-lag power factor. We agree that there is very little, if any, saturation in the machine at the pull-out point (particularly if the terminal voltage has decreased). However, saturation should be considered in that it does determine the internal voltage (or field current) which exists at the initial loading—this value of internal voltage then being constant in the case of pull-out under fixed excitation.

As to whether the generator feeds directly into an infinite bus or whether external reactance must be considered, thus allowing the terminal voltage to vary, depends, of course, entirely on the system under consideration. What may be justifiable in this respect on the Chicago system may not apply at all on other systems where there is more reactance between generators. This point is brought out in Appendix 1 of the paper but perhaps not too clearly. The data presented by Ward and Schroeder is a valuable addition to this phase of the problem.

Osterle asks whether it actually might be impossible to reach the steady-state pull-out point because the limit is above the turbine rating. It appears that this condition is possible if the terminal voltage stays close to 100 per cent. In this connection, the value of automatic voltage control is very apparent and as has been pointed out in oral discussions at the presentation, automatic voltage control in sufficient quantity practically eliminates the problem.

Table I. Comparison of Pull-Out Limits at Constant Excitation by Two Methods

Initial Loading on 147-Megawatt Unit of 0.5 Per Unit of Machine Megawatt Rating

Initial Power-factor	Pull-Out Limit in Per Unit on Machine Megawatt Rating: By Method of This Discussion	Pull-Out Limit in Per Unit on Machine Megawatt Rating: From Figure 2 of the Paper
0.9 lag	1.23	1.34
1.0	1.02	1.11
0.9 lead	0.83	0.90

In regards to loss of field, it is true that the terminal voltage of 60 per cent on loss of field, as shown on the curves, is the voltage on the terminal of that machine and the other machines at this same station. The generators at other stations would be at a somewhat higher voltage, but not much on the Chicago system because of the low reactance between stations. Hence, if nothing were done to remove the generator that has lost its field from the system, some of the other generators would pull out of synchronism, resulting in still lower voltages. Loss-of-field relays on the larger machines to remove the machine on loss of field from the system automatically are the answer to this problem.

Ward's analysis of treating the equivalent system consistently as a noninfinite equivalent machine is very interesting and certainly will apply on a large number of systems. Where the assumption of an infinite system cannot be made, his or some similar method[1] should be used, such as Figure 11 of the paper, wherein the method of handling this circuit is similar to the method of Ward neglecting the first term of his equation *1*. However, his own figures tend to prove the validity of the assumption of an infinite system when the equivalent system reactance is 0.1 on 100 megavolt-amperes or less. Such an assumption, of course, permits rapid and easy solution without involving the use of an a-c network analyzer. It is recognized that the infinite system assumption must give results that are on the optimistic side by a small amount which can easily be determined from the order of magnitude of the equivalent system reactance.

Adjusting the pull-out limits in proportion to the actual terminal voltage at the time of pull-out is, of course, permissible only on the infinite system assumption and was not intended as a general procedure. If the equivalent system is assumed zero reactance, then the pull-out power must vary directly with the terminal voltage. Note the close agreement obtained for pull-out of a generator when another machine has lost its field—by Mr. Ward's method the generator pull out is 0.62 of that shown in Figure 2 of the paper; by the authors' method, the generator pull-out is 0.65 of that shown in Figure 2, the generator terminal voltage being 0.65 at this time. The same argument holds true for a rise in system voltage on loss of a machine that has been operating at a leading power factor. It would appear that the pull-out margin required as pointed out in the paper must of necessity be large enough, taking all other assumptions into consideration, so that a minor discrepancy in calculated pull-out limits is of no serious consequence.

Location of Gas Leaks in Pipe-Encased Gas Pressure Cable Lines

JOHN D. PIPER
NONMEMBER AIEE

WHEN The Detroit Edison Company decided several years ago to install a gas pressure cable within a steel pipe for an approximately 7-mile 120,000-volt transmission line between Delray Power House and Warren Station, questions arose concerning means for locating gas leaks, should any develop. No method that could be expected to give reasonably reliable results was available, and accordingly a method had to be devised. The purpose of this paper is to describe that method.

The method is applicable for use with pipe-contained cables that operate under gas pressure, whether the gas is in contact with the insulation, as in gas pressure cable, or is separated from the insulation by a sheath, as in compression cables. In addition, it seems probable that, by introducing minor modifications, the method may be applied to self-contained gas pressure cables as well. The method has given good results both in locating a simulated leak at a joint in the pipe line, and in locating actual leaks in the terminals of the line mentioned.

To avoid the implication that pipe-contained gas pressure cables are inherently subject to leaking, it seems advisable to state that, except at terminals, no detectable leaks have thus far developed in The Detroit Edison Company's gas-pressure line.

Structural Features of Line

Structural features of the cable line pertinent to the development of the leak test are shown in Figure 1. Three single-conductor cables are contained in a steel pipe as shown in diagram A. Approximately 40-foot lengths of the pipe are welded together to form sections ranging from slightly less than 400 to nearly 1,500 feet in length. These sections, which contain continuous lengths of cables, are connected by joints in which the cables are spliced. Twenty-three of these joints are termed normal joints, diagram B, which provide a continuous gas passage. Near the end of each joint is a gas sampling valve. The other six joints are stop joints, diagram C. Each provides a gas barrier. The barrier is shunted by a by-pass in which a by-pass valve, normally kept open, is located. A test valve is located on each side of the by-pass valve. The stop joints, two of which are at the ends of the pipe line, separate the line into five stop-joint-to-stop-joint sections, as in diagram D. In addition, there are two terminal sections as shown. In these, the three cables run from the stop joint to their respective potheads in three separate pipes called sweeps. A test valve is located at the base of each pothead.

The line operates under a nitrogen pressure of approximately 200 pounds per square inch. The volumes of the gas space surrounding the cable in the sweeps, the pipe line, and the joints are known with fair accuracy, and the average temperature of the gas is obtainable from measurements made at several thermocouple stations.

Requirements of Test Method

The first requirement of the test method was that the use of it would not adversely affect the cable. A second was that service of the line should be interrupted as little as possible. Preferably, service should be interrupted only if it became unfeasible to keep the line at operating pressure. The third requirement was that the method be sufficiently sensitive to detect and locate the minimum size of leak that would be sought. Originally this value was set at one tankful, or 200 cubic feet at atmospheric pressure, of nitrogen per day. Later, when it became apparent that the method was sufficiently sensitive to reveal leaks of much smaller magnitudes, it was decided that the presence of these smaller leaks should be detected as they occurred but should not necessarily be located.

Practically all of the methods used for locating leaks in manufactured or natural gas lines were eliminated by the requirements, especially that of the minimum rate, which is much lower than that tolerated by most gas companies for the same length of line. Most odorants, including those used in manufactured or natural gases, were considered objectionable because they might be absorbed by, and deleteriously affect, the insulation of the cable. In addition, the odorants would be absorbed by the soil, thus diminishing their effectiveness, and, especially in paved areas, might travel in underground passageways a considerable distance from the leak before emerging from the ground. Because the gas used in the cable line was nitrogen, methods based upon the effect of the escaping gas on vegetation were of no avail and detection of nitrogen as it escapes into the air was considered impractical.

Test methods involving radioactive tracer gases were also considered but were rejected because, among several other reasons, they might promote ionization in the cable and be dangerous to personnel. Use of combustible and toxic tracer gases was also rejected because of possible danger to personnel or equipment.

Methods based upon the resistance of

Paper 48-3, recommended by the AIEE transmission and distribution committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted April 21, 1947; made available for printing November 13, 1947.

JOHN D. PIPER is with the research department of The Detroit Edison Company, Detroit, Mich.

The author is grateful to the following colleagues, past and present, for their contributions to the principles, instruments, and data described herein, E. B. Baker, Eugene Brown, F. M. Hull (A'33), M. R. Lewis, R. J. McCausey, and Franklin Schlachter.

flow of gas through the line, such as are used for locating gas leaks in telephone cables, could not be used because the resistance to flow through the 7-inch pipe line is negligible as compared with the resistance of flow through the test valves. These valves furnish the only practical means by which instruments for determining conditions within the gas space could be attached. Stethescopic and other listening devices proved to be unsuccessful because of other noises.

Principle of Method Adopted

The method finally adopted consists of three steps. Step 1 shows which, if any, stop-joint-to-stop-joint or terminal sections contain leaks and the rate of each. Step 2 locates a leak within a stop-joint-to-stop-joint section to the affected joint-to-joint section. Step 3 locates a leak within a joint-to-joint or terminal section with respect to a selected point, such as the position of a test valve.

Step 1 depends upon the principle that, if gas escapes from a space of constant temperature and volume, the pressure drops. If the temperature remains constant the rate of the gas leak is proportional to the product of the volume of the gas space and the rate at which the pressure drops.

The principle of Step 2 is illustrated in Figure 2. A tracer gas is introduced, as shown by ↓ diagram *A*, at the gas sampling valve of a normal joint near the midpoint of the affected stop-joint-to-stop-joint section. The rate at which the tracer gas is introduced is adjusted to compensate exactly for the rate of the leak. The tracer gas migrates toward the leak resulting in a column that extends a short distance from the point of introduction, as shown. After a chosen quantity of the tracer gas has been introduced, the source of supply is removed and is replaced by a gas analyzer. A quantity of nitrogen equal to half that of the tracer gas is then introduced rapidly at the joint next to the analyzer in one direction and is withdrawn simultaneously at the joint next to the analyzer in the opposite direction. If the leak happens to be in the direction from which the nitrogen was introduced, the column of tracer gas is brought beneath the sampling valve, as in diagram *B*, with the result that the analyzer indicates the presence of the tracer gas. If, on the other hand, the leak happens to be in the opposite direction from which the nitrogen was introduced the column is pushed away from the sampling valve, as in diagram *C*, and the analyzer shows the gas to be nitrogen. In this case the direction toward the leak is confirmed, diagram *D*, by pushing the column in the reverse direction until it is beneath the sampling valve. For effecting the latter shift, the points of introduction and withdrawal of the nitrogen are reversed and the quantity used is equal to the quantity of tracer gas introduced.

Real gases, of course, mix in all proportions. The reason the method can be used is that the rate of diffusion is slow. Pronounced mixing of the gases does take place, however, both because of diffusion and of the turbulence created when the tracer gas is introduced or shifted. Diagrams *E*, *F*, and *G* show that for real gases the indication given by the analyzer cannot be expected to show that the tracer gas is simply present or absent. Some always will be present. The direction toward the leak can be determined readily, however, by the change in readings with time during the shifting of the column as described later.

After the direction toward the leak is determined at a joint near the center of the affected stop-joint-to-stop-joint section, the procedure is repeated at a joint near the center of the affected half and so on until the affected joint-to-joint section is located.

- Sampling point (same point as above)
- Direction toward leak
- Direction of force that pushes column a distance equal to half its length
- Direction of force that pushes column a distance equal to its length
- Column of real tracer gas showing diffuse edges

The principle of step 3, illustrated in Figure 3, is similar to that of step 2. The tracer gas is introduced at one end of the affected joint-to-joint section at a rate to compensate exactly for the leak the same as in step 2. The quantity introduced is sufficient to displace all of the nitrogen in that section. As the tracer gas is introduced the front of the column migrates toward the leak. When the leak is reached, the tracer gas, instead of nitrogen, leaks out, thus disposing of the excess. At the same time the introduction of the tracer gas is completed,

therefore, a column of the tracer gas extends from the joint at which it was introduced to the leak, and a column of the original nitrogen extends from the leak to the joint at the opposite end of the section, designated by E in diagram A. Gas is then withdrawn rapidly at E and is metered and analyzed. Simultaneously nitrogen is introduced at the other end of the section at a rate equal to the rate of withdrawal plus the rate of the leak. The first gas metered is nitrogen. Its volume is indicative of the distance from the leak to E. The position of the tracer column is then as shown in diagram B. From the time the column of tracer gas is shifted from its position, as in diagram A, until its trailing end passes the leak as shown in diagram C, some of it is being lost through the leak. Finally, the last of the tracer gas is removed from the section as shown in D. The quantity of tracer gas metered plus the quantity that escapes while the column passes the leak is indicative of the distance to the leak from the joint at which the gas was introduced.

Interferences

As is evident from the foregoing principles, a sensitive means for determining pressure changes is necessary for all three steps of the test. A leak of one tankful of nitrogen (200 cubic feet at atmospheric pressure) per day in an average stop-joint-to-stop-joint section of the gas pressure cable line would result in a loss of pressure of approximately 0.1 pounds per square inch per hour. During the normal working hours the pressure increases as the result of load and ambient changes at an average rate in excess of 0.25 pounds per square inch per hour. For this reason the differential pressure change across a stop joint, instead of the change in gauge pressure, is used to determine the change in pressure resulting from a leak in any section.

This differential pressure is measured by means of a differential oil-manometer. Obviously this method can be used only if at least one stop-joint-to-stop-joint section is leak free.

Not all differential pressures across a stop joint are caused by leaks. The most conspicuous of these interfering differential pressures are those exhibited by a rapid up-and-down motion of the oil in the differential manometers. The oil levels in the legs of the manometers have been observed to surge up and down several times per minute in amplitudes as high as fourteen inches. Usually these surges, hereafter called waves, are not present. Inasmuch as large waves have been observed to develop within two hours it is necessary to eliminate the interference they introduce in the measurement of pressure changes resulting from leaks, which may be only a few hundredths of an inch of oil per minute. Fortunately the interference caused by the wave motion, which is rhythmic in character, may be almost entirely eliminated, as will be described later. More troublesome to eliminate than the effect of the rhythmic motion of the waves is the effect of entrapping a wave crest as the stop-joint by-pass valve is closed. Only as the excess gas from the wave becomes distributed evenly in the section in which it was caught does the average differential pressure become constant.

This differential pressure may amount to several inches of oil and as much as an hour may be required for equilibrium to take place. The change in the differential pressure resulting from entrapment of a wave may be distinguished from that caused by a leak by the

fact that whereas the rate of change diminishes with time in the former case, it remains constant in the latter.

Another source of differential pressure which interferes with those caused by leaks is that caused by unequal rates of heating and cooling in different parts of the line. For example, in the line on which the development was carried out, the section at one end is not buried as deeply as the rest of the line. This section, as might be expected, apparently heats up more rapidly than the rest of the line during the day and cools more rapidly at night. The rates at which the resulting differential pressures change at the stop joint between this section and the rest of the line are at times as great as those that would result from a leak of approximately half a tankful of nitrogen per day. This interference is eliminated, when necessary, by extending the test period over a 24-hour interval during which time the differential pressure that builds up in one direction during the daytime is cancelled by the differential pressure that builds up in the other direction at night.

For steps 2 and 3 there is another interference that results from the mixing of the tracer gas with the nitrogen. As previously stated, considerable mixing takes place by turbulence and diffusion as the tracer gas is introduced through the narrow-throated test valve into the joint. Further mixing takes place as the column of tracer gas is pushed along the pipe, as might be expected because the three cables within the pipe make the gas space

irregular in shape. The means by which the interference caused by the mixing of the gases is minimized is described later.

Procedure and Equipment

Recommended practice is to test the cable line for the presence of leaks periodically, say once every six months, by means of "Step One." Any leaks present are thus located as to the affected stop-joint-to-stop-joint or terminal section. Step 2, if required, and step 3 are then applied whenever it becomes expedient to do so. Inasmuch as the tracer gas must be introduced no faster than the rate of the leak, there is a minimum size of leak that is economically expedient to attempt to locate by means of steps 2 and 3.

Because the successive steps progressively narrow the region in which a leak need be sought, use of auxiliary tests may eliminate the need for carrying the systematic, stepwise procedure to completion. These auxiliary tests include patrolling the line for obvious mechanical evidences, and the usual methods for seeking gas leaks such as listening, and applying soapsuds or water around joints at manholes.

The stepwise procedure is preferably carried out with the line in normal operation. In order to minimize thermal gradients, the line should not be shut down during leak tests, unless it is desirable in order, either to safeguard the cable, or to close the by-pass valves on the affected section for the purpose of saving the gas. For leaks so large that shutdown of the line is necessary, the effect of the differential pressures caused by thermal gradients is negligible as compared with those caused by a leak.

Description of the stepwise procedure and the equipment required is given in the following sections.

Step 1

For routine inspection of the line for leaks, according to step 1 a manometer is placed in operation across each of the stop joints that connect the several stop-joint-to-stop-joint sections. The by-pass valve on each of these stop joints is closed and the differential pressures that result between the several sections are allowed to accumulate simultaneously. Readings are taken on each manometer several times during the course of the first day of the test and again several times on the second day. Between readings the manometers are left unattended unless the rate of change of the differential pressure is so great that the range of the manometers

Figure 6. Graphical method for determining the rate of change of the differential pressure at a stop joint (when wave conditions are simple)

might be exceeded before the next reading period. Tests at the terminal stop joints are usually made separately, on the line under discussion, because the volumes of the gas space in the terminal sections are so small that the presence of any significant leak is easily detectable within such a short time that nothing would be saved leaving the manometers unattended.

The manometer assembly used, shown connected across a stop joint in Figure 4, was designed to be left unattended. Inasmuch as all tests are run with the line in operation it was necessary that some means be provided to enable those responsible for the operation of the line to be warned should a sudden leak develop, such as by mechanical accident, while the manometers are in operation unattended. As previously stated, the stop-joint by-pass valves are kept open during normal operation. The pressure of the entire line is then continuously indicated by instruments connected to the gas space of the terminal sections. Closure of more than one stop-joint by-pass valve, which of course is necessary if several manometers are operated simultaneously, isolates part of the line from the instruments except for the flow that would take place through the manometer tubing should the range of the manometer be exceeded. Because even the best glass tubing is not infallible, it seemed advisable to shut off the manometer proper while the assembly is left unattended. In order to provide a mechanism for communicating across a stop joint any excessive pressure differential that might develop while a test is in progress and the manometer proper is shut off, metal tubing i, i^1, Figure 4, was placed in parallel with and extended slightly below the manometer tubing. This metal tubing is filled with oil to approximately the same level as that in

Figure 7. Comparison between graphical and algebraic average methods for determining the rate of change of the differential pressure at a stop joint when wave conditions are complicated

Note: Rate of change of the differential pressure, inches of oil per minute, equals twice the slopes of the lines

the manometer. The oil prevents transfer of gas across the stop joint until a differential pressure of somewhat over fifty inches of oil is built up, whereupon the oil is discharged into one of the anti-splash bulbs, f, f^1, leaving a free path for gas transfer.

Operations preliminary to the use of the manometers consist in attaching them across the stop joints as in Figure 4, bringing the manometers to line pressure, and testing them to insure that the metal tubing contains sufficient oil and that all connections are leak free. Before bringing the manometer to line pressure the manometer by-pass valve, (h) is opened. One of the two test valves on the joint is then opened slowly, bringing the manometer to line pressure. The connection at the other test valve is next cracked slightly in order to allow displacement of the air within the manometer. The connection is then tightened until the escaping gas makes only a barely audible hiss after which valve (h) is turned cautiously toward the closed position until the oil levels in the manometer become displaced nearly to full scale, thus showing that the parallel metal tubing, in which the oil levels are not visible, contains sufficient oil. Valve h is then opened, the connection is tightened, and the test valve on the stop joint is closed. To determine whether any leaks exist in the connections valve h is next closed. Because the volume of the gas space in the manometer and connections is small, the presence of any leak is quickly evident by the shifting of the oil levels. If any are present their locations are sought by means of soapsuds and are eliminated. Both test valves on the joint are then opened. In general all manometers are installed and the tests herein described are made before the reading period is started.

To start the reading period, the stop joint by-pass valve is closed and the time is noted. Readings are taken over an interval of approximately 15 minutes, whereupon—unless the levels are changing at a rapid rate—the manometer valves are closed. Initial readings are then taken on other manometers in turn. Both the manometer by-pass valve, (h) Figure 4, and the stop-joint by-pass valve are kept closed between readings. Subsequent reading periods may usually be reduced to approximately five minutes.

In the absence of waves the taking of the readings is conventional. In the presence of waves it is convenient to read only one leg of the manometer. Simultaneous readings are taken of the time and of the oil level at one or more characteristic parts of the wave, usually the maximum height to which the oil level rises in one leg of the manometer and the minimum height to which it falls.

Typical wave behavior is shown in Figure 5 in which the points representing successive readings of maxima and minima are connected by lines. This figure also illustrates the phenomenon of entrapment of a wave crest, previously mentioned as one of the interferences that must be overcome. Apparently wave forms may vary from simple sine waves to complicated forms resulting from interference and reinforcement phenomena. All waves, however, appear to go through a repetitive cycle, the recognition of which permits the effect of the wave to be practically eliminated.

For simple waves, in which the amplitudes of successive waves are essentially constant, the effect of the wave is conveniently eliminated graphically, as in Figure 6. In this figure the points representing successive readings of the maximum height to which the oil rises in the manometer are connected by one straight line and the points representing successive readings of the minimum height are connected by another. The average slope of the two lines gives a measure of rate at which the differential pressure across the stop joint is changing. Because the readings are taken on only one leg of the manometer, the slope of the line is multiplied by 2 to obtain the rate of change of the differential pressure in inches of oil per minute, designated in Figure 6 as Δp/min.

For cases in which the differential pressures are accumulated on the manometers over a period of several hours, the wave form may change. If the wave form changes the effect of the waves is best eliminated by determining the algebraic average of all maxima and minima readings that are taken over a complete cycle. Using this average and the time of the midportion of the cycle to establish a single point, the slope of the line that connects several such points is determined.

Usually a complete cycle may be recog-

nized by inspection of the manometer readings. Figure 7 gives an example of a case, the most complicated thus far experienced, in which recognition, without the plotting of the data, would have been difficult. In this figure the points representing successive readings of the maxima are connected, and likewise those representing the successive readings of the minima. The marked reinforcement and interference of the waves, and the approximate three-minute lag from the time the displacement of the oil level was greatest in negative direction until it became greatest in positive direction are evident. The midpoints of each time interval over which a complete cycle of readings was taken and the algebraic averages of the readings for each cycle are given by the X's at the bottom of the figure. A line connecting these X's has a slope of 0.0096 inch per minute as shown.

For the illustration in question it is evident that the character of the wave did not change over the period of these readings. For cases in which it is unnecessary to combine such readings with others taken when the wave form is different, it is more convenient, as previously stated, to effect a graphical solution. The graphical solution for the complicated set of data in question is included also in Figure 7. There a line is drawn through the points representing the strongest maxima, and another through the points representing the strongest minima. The average slope of these two lines agrees well with that determined from the algebraic averages.

Elimination of the effect of the rapid up and down wave motion leaves a more or less slowly changing differential pressure across a stop joint which may be the result of a leak, thermal inequalities, or the entrapment of a wave crest. That resulting from a leak is of a practically constant rate; that from thermal inequalities may be nearly constant over several hours, but during the course of a day changes rate and direction; that caused by the entrapment of a wave crest diminishes with time after the first several minutes as previously illustrated in connection with Figure 5. The effect of the latter two is therefore minimized by extending the test period. In practice, the average rates at which the differential pressures change when the line is leak-free are determined for test periods of various durations, and these rates are used in interpreting results.

The direction toward a leak is, of course, the direction toward which the oil column in the manometer rises. The rate, in cubic feet per day, is the product of the rate at which the differential pressure, in inches of oil (specific gravity 0.885) per minute, changes, multiplied by the volume of the section in cubic feet, by the conversion factor 3.13 which converts inches of oil per minute to atmospheres per day.

With several manometers in use simultaneously it is obvious that if a leak is present in any section that is between two manometers, the rate of differential pressure change at both should be identical. Any lack of agreement between the two, beyond the probable limits due to thermal inequalities, is evidence that leaks exist in more than one stop-joint-to-stop-joint section. Procedures for locating multiple leaks, whether in different stop-joint-to-stop-joint sections, the same stop-joint-to-stop-joint section but different joint-to-joint sections, or in the same joint-to-joint section, have been worked out in principle but are beyond the scope of this paper. Likewise procedures have been developed for locating leaks that are so large that the line must be shut down and the stop-joint-by-pass valves closed to conserve gas. All of these procedures, which are too detailed to be included but which are based upon the same principles as the general procedure described, are available to anyone interested.

Step 2

Location of a leak to the affected joint-to-joint section, by the method described in this paper, requires

1. A supply of tracer gas.
2. Equipment for introducing the tracer gas into the line at a rate equal to the rate of the leak.
3. Nitrogen supply and other apparatus for shifting the column of tracer gas along the line.
4. An analyzer for differentiating between the tracer gas and the nitrogen with which the line is normally filled.

The tracer gas selected and used to date is a mixture of five per cent by volume of carbon dioxide in nitrogen. Carbon dioxide was chosen in preference to other gases because its sparking potential is

Figure 10. Assembly of equipment at a manhole at which tracer gas is introduced for step 2

Figure 11. Typical data during the shifting of the column in step 2 showing leak to be in direction from which the nitrogen was introduced. Volume of tracer gas introduced—73 cubic feet

*—During shift period 36 cubic feet of nitrogen introduced at the adjacent joint in one direction from the analyzer and withdrawn at the adjacent joint in the opposite direction

even higher than that of nitrogen, because it is obtainable commercially in fairly pure form, and because its use presents no hazard to either personnel or equipment. The proportion of carbon dioxide to nitrogen was kept as low as practical because even the purest carbon dioxide that is commercially available often contains more moisture than is permissible in the cable-gas according to specifications.

In order to minimize the number of tanks of gas required for storage, it was considered more expedient to make up the mixture of tracer gas as required, in the tanks ordinarily used to store the nitrogen, instead of purchasing and storing the mixture. For making up the mixture a manifold having ten places for nitrogen tanks and one place for a carbon dioxide tank is used. It is required that the moisture content of the carbon dioxide be not in excess of 0.35 grams per cubic meter at atmospheric pressure and that the nitrogen have a dew point, at 2,000 pounds per square inch or greater, not higher than 0 degrees Fahrenheit. Thus the moisture specification of not exceeding 0.0025 per cent water by weight in the gas mixture is readily met. Usually step 2 requires no more than four 200-cubic foot tankfuls of the tracer gas but inasmuch as step 3 requires a considerable number it may be convenient to prepare those required for both steps at the same time.

The equipment for introducing the tracer gas at a rate equal to the rate of the leak consists of a tank of the gas, a nitrogen regulator, a capillary regulator, a differential oil manometer, and the necessary connecting tubing. The nitrogen regulator is of conventional type, having a pressure gauge on both the high and the low pressure side. It should furnish regulation up to 300 pounds per square inch. The capillary regulator is shown in Figure 8. It consists of three capillary tubes mounted in parallel within protective covers, as indicated by *A*, *B*, and *C*; bypass *D* in parallel with the capillaries; valves (a), (b), (c) and (d) controlling *A*, *B*, *C*, and *D* respectively; exhaust regulator *E* mounted beyond the line end of the capillaries and containing gauge *G* on its high pressure side; chamois filter *F* to protect the capillaries from dust that may be in the line; connections *H* and *I* to the line and to the tank regulator respectively, and mounting panel *J*. The capillaries consist of *18-8* stainless steel hypodermic needle tubing of various sizes progressing from the smallest at *A*. The manometer has been previously described.

To effect the desired shift of the column of tracer gas it is necessary to introduce a given volume of nitrogen at a joint in one direction from the column and withdraw an equal volume at another joint in the opposite direction. The equipment required to introduce the nitrogen consists simply of a tank of nitrogen, a tank regulator, and connecting tubing. The volume introduced is measured with sufficient accuracy by the change in volume indicated by the volume scale of the high-pressure gauge. The equipment used to remove the required volume of nitrogen consists of an iron-case gas meter, a valve, and connecting tubing. The meter is a so-called *20-B* size rated at 350 cubic feet per hour at a pressure differential of 1/2 inch of water and 700 at two inches.

The dial can be read to 0.1 cubic feet, a feature necessary for step 3, with which it also is used. The analyzer was made specifically for the job after it was found that a commercial analyzer, around which the procedure was built, was too sensitive to temperature changes to be used by field personnel. With other commercial analyzers, either too large a flow of gas was required for their operation, or too large a current flow was required to permit operation by dry batteries as the current source. At the time the method was being developed, instrument makers were too busy with war work to be bothered with making a suitable instrument.

The analyzer operates on the usual principle which depends upon the difference in thermal conductivity of gases. A unique feature is a plug-type cock which in one position permits the reference gas, dry nitrogen, to contact both elements while the gas to be analyzed is exhausted, or in the reverse position permits the reference gas to contact only one element while the gas to be analyzed contacts the other. Thus the zero point of the analyzer may be checked quickly and easily. The active elements, made from General Electric Mazda *24X* telephone light bulbs, are matched as closely as possible both for resistance and for change in resistance with temperature change. The effect of temperature change is further minimized by suspending within a manhole during use, both the brass cell, which contains the active elements, and the batteries as shown in Figure 9. Nitrogen for reference gas is supplied through a nitrogen regulator and orifice, which conveniently may be one capillary of the terminal cap-

Figure 12. Typical data showing leak to be in the direction from which the nitrogen was withdrawn during the first shift period of step 2. Volume of tracer gas introduced—32 cubic feet

*—During first shift period 16 cubic feet of nitrogen introduced at the adjacent joint in one direction from the analyzer and withdrawn at the adjacent joint in the opposite direction
**—During second shift period (confirmatory test) 32 cubic feet of nitrogen introduced and withdrawn at joints in directions reversed from those referred to above

illary regulator to be described in connection with tests made at terminals in step 3.

The first operation in step 2 is to assemble the equipment as shown in Figure 10 with the tank of tracer gas connected in series with its tank regulator and the capillary regulator. The latter is connected in turn to the joint that is near the midpoint of the affected stop-joint-to-stop-joint section. A manometer is connected across a stop joint that is between the affected section and a leak-free section. The rate at which the tracer gas is fed is adjusted in such a way that the oil levels in the manometer remain constant. To do this the tank regulator is adjusted until its low pressure gauge reads a few pounds higher than the line pressure as shown by the line pressure gauge on the capillary regulator. Through choice of one or more capillaries on the capillary regulator and the differential pressure across them, the rate of introduction is controlled easily over a wide range. The volume introduced is, for the line in question, from 30 to 60 cubic feet at atmospheric pressure, depending principally upon the extent to which thermal gradients effect a change in differential pressure at the stop joint containing the manometer.

During the introduction of the tracer gas the analyzer is assembled with the suspended parts clamped to one of the two manhole covers as shown in Figures 9 and 10, and the equipment for shifting the position of the gas column is assembled at the adjacent joints. The analyzer is placed in operation with the handle of the plug valve, Figure 10, protruding above the closed manhole cover, set in such a position that nitrogen from the tank comes in contact with both elements. The bridge arms of the analyzer are adjusted to give a zero reading of the galvanometer under these conditions. After the desired volume of tracer gas has been introduced the manometer valves on the stop joint, some distance away, are closed. The valves on the capillary regulator are then closed, and the supply connection to the capillary regulator is replaced by the adapter, tubing from which connects to the port on the cell at which gas to be analyzed is introduced. Valve "a," Figure 8, controlling the smallest capillary on the capillary regulator, is then opened and the handle on the plug cock is reversed, allowing a slow stream of gas from the joint to flow through the analyzer. After a few minutes the column of tracer gas is shifted in a selected direction as described previously.

Figures 11 and 12 show the manner in which the analyzer readings are interpreted to show the direction toward the leak. In both figures the analyzer readings drop rapidly at first as the undiluted tracer gas is exhausted from the connecting tubing. A slow decline then follows as the column drifts toward the leak. In this connection it should be pointed out that if for proper operation the analyzer requires a rate of flow more rapid than the leak the column will drift back toward the analyzer and may obscure the indication. Upon the deliberate shift of the column the analyzer reading increases suddenly, as shown in Figure 11, provided the leak is in the direction from which the nitrogen was introduced. Conversely, the analyzer reading decreases suddenly, as in Figure 12, if the leak is in the direction from which the nitrogen was withdrawn. In the latter event a confirmatory test is made by shifting the column in reverse direction. For this second shift the volume of gas introduced at one joint and withdrawn at the other is equal to the volume of tracer gas originally introduced. During the second shift the analyzer reading increases sharply, thus confirming the direction toward the leak.

Before similar tests are made near the midpoint of the part of the stop-joint-to-stop-joint section in which the leak has thus been indicated, it is necessary to purge the line of traces of the carbon dioxide. To do this the exhaust valve on the capillary regulator is opened and readings are continued. Typical data are shown in Figure 13. After most of the tracer gas has thus been purged and the analyzer readings approach zero, nitrogen is introduced at one or the other of the adjacent joints, thus shifting the column of the residual gas. The purpose of the

Figure 13. Field data representing the purging of the tracer gas from the line

shifting is of course to center the remaining tracer gas around the valve through which the gas is being withdrawn. Such shiftings, if in the right direction, cause temporary increases in the analyzer reading. If in the wrong direction, as indicated by a sudden drop in readings, nitrogen is introduced from the opposite direction. Purging is continued until the analyzer reading drops to zero and remains at zero as the nitrogen is introduced from each side. The section is then brought up to normal pressure with nitrogen, and the test is repeated at the other joints as described previously, thus locating the leak to the affected joint-to-joint section.

Initial Meter Reading 121 Cubic Feet

Figure 16. Graphical estimation of volumes of gas columns

	Volume Nitrogen Cu Ft	Volume Tracer Gas Cu Ft
Metered	1520-121=1399	2268-1520=748
Unmetered through analyzer	0.1 cfm×211 min=21	0.1 cfm×102* min=10
Through leak		0.51 cfm×121* min=62
Total	1420	820

Note: Time intervals marked * would have been identical if rate of metering had been constant.

Step 3

In general the equipment required for step 3 is the same as that required for step 2. The procedure is similar in many respects. Tracer gas is introduced at a rate to compensate for the leak, utilizing a reference manometer at one of the stop joints of the section involved, as described in step 2. The gas is introduced at one end of the affected joint-to-joint section. Introduction is continued until the volume introduced is approximately five per cent in excess of the volume of gas in that section. The rate of introduction can be so accurately controlled that the presence of an operator is required only a few hours a day after the first day. For leaks having rates much greater than a tankful per day a manifold is required at the feeding station as shown in Figure 14. This figure shows the arrangement of the feeding equipment in a splicer's shanty for a case in which the gas is introduced at a stop joint that can be used for attachment of the reference manometer. Usually, however, the manometer will be in a manhole at the reference stop joint some distance from the feeding equipment.

After the required volume of tracer gas has been introduced the next operation is to shift the columns. Before discussing the equipment and procedure required for this operation, it is desirable to recall that the operation consists of the following steps:

1. Removing rapidly the entire gas content of the joint-to-joint section from one end of it.
2. Metering and analyzing this gas as it is removed.
3. Introducing nitrogen at the other end of the section at such a rate as to compensate both for the rate of removal and the rate of the leak.

During the shifting of the column it is essential that a means of instantaneous communication be provided between the person watching the reference manometer and the one introducing the nitrogen. Unless these two persons happen to be close together, telephone or radio service is required.

Preparations for shifting the column of gas consists of the following steps:

1. Replacing the capillary regulator at the feeding end of the affected section by a needle valve. During this change the feeding of the tracer gas is not interrupted longer than is necessary.
2. Replacing all but one of the tanks of tracer gas on the manifold by tanks of nitrogen.
3. Attaching the capillary regulator, gas meter, and analyzer in position at the end of the section from which the gas is to be withdrawn.

The arrangement of this equipment is similar to that used in step 2 except for the position of the gas meter which is attached to the exhaust valve of the capillary regulator as shown in Figure 15. The analyzer is set in operation, with the plug cock in test position, allowing nitrogen to flow through both elements, as previously described. Preparations are completed by stationing operators at the three locations involved, namely the joint at which the gas is to be removed, the joint at which the feeding of the tracer gas has been conducted, and the reference manometer, which, as previously stated, is at a stop joint that separates the leaky stop-joint-to-stop-joint section from a leak-free stop-joint-to-stop-joint section. The operations described in the next two paragraphs are carried out simultaneously.

At an appointed time, gas from the joint to which the capillary regulator is attached is admitted through the smallest capillary A, Figure 8, to the analyzer, the plug cock of which is then turned to the

Figure 15. Arrangement of equipment for withdrawing, metering, and analyzing the gas during step 3

"analyze" position. The analyzer and meter readings and the line pressure are noted, after which the exhaust valve is opened gradually over the course of a few minutes until the gas is being withdrawn at a rate sufficient that the entire content of the leaky joint-to-joint section will be removed in approximately four to six hours. This rate is maintained constant during the column-shifting operation. During this operation simultaneous notations are made every few minutes of the time, meter and analyzer readings, and the temperature of the exhausted gas. Occasionally the differential pressure between the meter and the atmosphere is noted on the manometer that is shown mounted on the meter, Figure 15. Also the pressure at the entrance to the capillary regulator is noted. This pressure reading is used with a calibration curve in determining the volume of gas that escapes through the analyzer.

At the appointed time referred to in the preceding paragraph the supply of tracer gas is shut off at the feeding manifold and a tank of nitrogen is turned on. At the reference manometer, a displacement of the oil levels results from the removal of gas through the capillary regulator. Information concerning the displacement is communicated to the operator at the feeding manifold, whereupon the rate of introduction of the nitrogen is adjusted to keep the manometer balanced.

The first gas that is metered and analyzed consists, as explained in the principles, of the nitrogen that was originally in the section. This nitrogen is followed by the tracer gas, and this in turn is followed by the nitrogen that was introduced as the shifting of the column was started. After all the tracer gas has been removed, the exhaust valve is closed and the final pressure of the line is noted. This may be slightly different from the original pressure, owing to loading and ambient changes. Care is taken to purge from the adjacent ends of the adjoining sections any of the tracer gas that may have entered these sections during the introduction of the tracer gas or the shifting of the column.

As stated when the principles were discussed in connection with Figure 3, the volume of the column of nitrogen that was in the section before the column was shifted is a measure of the distance from the valve at which it is removed to the leak, and the volume of the column of tracer gas is a measure of the distance from the valve at which it was introduced to the leak. As also stated, a part of the tracer gas is lost as the column passes the leak. The volume lost is the product of the rate of the leak, which is known from "Step One," and the time required for the column to pass the leak. If the gas is withdrawn at a constant rate the time required for the column of tracer gas to pass the leak is

$$\frac{v_t}{v_t+v_n}\times t$$

where

v_t = metered volume of tracer gas
v_n is the metered volume of nitrogen
t is the total time required to meter both columns

In addition to the gas lost through the leak, a part passes through the analyzer. The rate at which this gas escapes is obtainable by means of a calibration curve from the pressure indicated by the gauge on the capillary regulator with the exhaust valve open. The product of this rate by the time required for each gas to be metered gives the respective values of unmetered gas passed through the analyzer. These unmetered volumes are added to the metered volumes as subsequently described.

Because the line of demarcation between the tracer gas and nitrogen is not absolutely sharp, the volumes of the respective metered gases and the times required for metering them may best be solved graphically. Figure 16 shows field data for the simulated leak to which reference has been made. The analyzer readings remained essentially 0 from the initial meter reading of 121 cubic feet to approximately 1,400 cubic feet. The analyzer readings then rose sharply as shown, then more gradually. Next, they dropped sharply and then more gradually toward 0. Interpretation of where one column ends and the other begins may vary slightly for different interpreters. For use by field personnel, it seemed desirable to adopt the following instructions which are illustrated in connection with the figure:

1. Draw a line tangent to the curve through the point of inflection, that is, through the greatest number of consecutive points in the major rise in the curve that indicate the appearance of the tracer gas.

2. Draw a similar line through the points that indicate the disappearance of the tracer gas.

Figure 17. Terminals showing sampling valves immediately beneath the potheads

Figure 18. Terminal capillary regulator and analyzer connected as used for terminals

3. Draw a third curve across any flat part of the points representing the maximum readings obtained. This curve, which is not necessarily a straight line, will generally slope upward because the trailing remainder of nitrogen in the irregular spaces between the cables is gradually swept out as more of the tracer gas passes by it. Variations in composition of successive tankfuls of tracer gas may also contribute to deviations from a straight line. The curve so drawn intersects both with the line showing the appearance and with that showing the disappearance of the tracer gas.

4. Find the midpoint between the intersection and zero analyzer reading on the line representing the appearance of the tracer gas. The meter reading corresponding to that midpoint is taken as the meter reading at the end of the nitrogen column and at the beginning of the tracer-gas column. (In the case illustrated in Figure 16, 1,520 cubic feet.)

5. Find the midpoint between the intersection and zero analyzer reading on the line representing the disappearance of the tracer gas. That midpoint is taken as the meter reading at the end of the tracer-gas column, or 2,268 cubic feet.

6. The difference between the reading at the end, and the reading at the beginning of the tracer gas column is the volume of tracer gas metered, or 748 cubic feet.

7. The difference between the reading at the end of the nitrogen column and the initial meter reading is the volume of nitrogen metered, 1,399 cubic feet.

After the meter readings corresponding to the appearance and the disappearance of the tracer gas column have been determined, the time intervals necessary for calculating the volumes of the unmetered gas are obtained from a plot of the meter readings versus elapsed time. The sums of the metered and unmetered volumes in the nitrogen and tracer gas columns under the conditions of temperature and pressure at which they were measured are then obtained as illustrated in Figure 16.

The volumes that the gas columns occupied, before the column-shifting operation, under the conditions of temperature and pressure existing in the pipe line are calculated by means of the gas laws. That is

$$V_1 = V_m \frac{P_m}{P_1} \frac{T_1}{T_m}$$

where

V_m = volume of the gas determined as described in connection with Figure 16

P_m = pressure of the gas in the meter = barometric pressure plus the pressure indicated by the meter manometer

P_1 = Average of initial and final pressure of line expressed in the same units as P_m

T_1 = Average temperature of the line, in absolute degrees

T_m = Average temperature of the gas at the meter during the metering of that column in absolute degrees

The gas space in the affected joint-to-joint section is considered to extend from the test valve on one joint to the test valve on the other. In the line in question these valves are not symmetrically spaced but are located near the ends of the joints. Thus both the column of nitrogen and the column of tracer gas consist partly of the space from valve to end of joint and partly of space within the pipe. The volume of the space within the joint is subtracted from the volume of gas calculated as previously described. The difference is the volume of the column of gas within the pipe. This difference, for each column, is then divided by the specific volume of the gas space within the pipe line to give the distance to the leak from the end of the joint at which the gas was removed and the end at which it was introduced, respectively. Thus the position of the leak is indicated by two independent measurements. Excavation is then made in the region so indicated and the exact spot is located either by means of soapsuds or by covering the pipe with water.

Terminals

A few important differences exist between locating leaks in terminals and locating them in joint-to-joint sections by means of "Step Three." At the terminals the three cables, instead of being in a single pipe, are contained, as previously stated, in separate tubes called sweeps. The three sweeps at each end of the line run from the terminal stop joints to their respective potheads as shown in Figure 17. Below each pothead is a gas sampling valve in the position shown.

During the feeding operation the tracer gas is fed at the stop joint to which the sweeps are attached and the reference manometer is used at the same stop joint in the manner shown in Figure 14. Instead of the usual excess of five per cent, an excess of approximately 25 per cent of tracer gas, based upon the calculated volume of the gas space, is used.

The gas for metering and analysis is removed separately from the test valve at the base of each of the three potheads. Whereas nitrogen is used at the feeding station to displace the gas removed during the column-shifting operation for joint-to-joint sections, the tracer gas is used for terminal sections. Metering and analysis of the gas from each of the three sweeps is discontinued as soon as the nitrogen column has been entirely removed from that sweep.

Because the volume of the gas space in the sweep per unit length is small when compared with that of the pipe between joints, gas is withdrawn much more slowly in order that an adequate number of analyzer readings can be taken per unit length of sweep. The rate of withdrawal is controlled by means of the terminal capillary regulator shown in Figure 18. This terminal capillary regulator consists of three capillary tubes that occupy the positions indicated by lines *1*, *2*, and *3*. Capillary *1* controls the rate of flow of nitrogen to the cell, and capillary *2*, the rate of flow of gas from the line. These two capillaries are of the same dimensions and, therefore, when the pressure of the nitrogen is adjusted to line pressure the rate of delivery of nitrogen and gas from the line is the same. Capillary *3* serves to conduct most of the gas from the line directly to the meter. Unlike the procedure for the joint-to-joint sections in which the gas required to run the analyzer is exhausted into the atmosphere and its volume is computed from the calibrated rate and the time involved, the gas required to run the analyzer during tests on terminals is metered. The metering is accomplished by reuniting the exhaust

from the line side of the cell with the gas that is shunted through capillary *3*, before the gas is passed through the meter. During the short periods in which the handle of the cell is turned in such a way that nitrogen is passing through both elements in order that the zero point may be adjusted, the gas from the line is being exhausted into the atmosphere and nitrogen from the cell is being admitted into the gas stream entering the meter. Because capillaries *1* and *2* are of the same dimensions, however, no error in meter reading is introduced.

Further differences include the necessary use of the cell and batteries above ground, as shown, instead of in a manhole; the use of a smaller-sized meter; and the necessity for flushing the tracer gas from the terminal section by introducing nitrogen at the test valves on each of the sweeps while withdrawing gas from the stop joint.

Accuracy

Experience with the method is thus far too limited to permit adequate estimation of its accuracy. Figure 19 presents data taken in the last step of the location of an actual leak which, by "Step One," was shown to be in a terminal section. The first of the gas removed from beneath the pothead on the X-phase was nearly half tracer gas. That from the Y-phase was practically all tracer gas. In the Z-phase, on the other hand, the presence of the tracer gas was not indicated until a volume of gas nearly equal to the volume of the gas space in that sweep had been removed. The data were interpreted to mean that the major part of the leak was in the Y-phase, at or beyond the test valve below the pothead and probably in the pothead itself and a secondary leak existed in the X-phase, near or in the pothead. The Z-phase was reasonably leak free. In this connection it should be pointed out that should a given section contain

Figure 19. Field data showing location of a leak in a terminal

Principal leak, pothead of *Y* phase
Secondary leak, pothead of *X* phase

more than one leak, the position of only one of the leaks will be accurately located during a single test. Procedures for locating secondary leaks have been devised but are too detailed for inclusion in this paper. In the case of the leak under discussion and treated by the figure, no confirmatory tests were run. The curves were, however, analyzed in some detail to give an estimate of the relative rates of the leaks in the two phases. The positions and relative rates were found, upon shutdown of the line, to be as predicted by the tests.

The only other information concerning accuracy was obtained during the test of the method by means of an artificial leak as has been described in part in several sections of this paper. The total length of the line is nearly seven miles. The length of the section upon which the final step was carried out was slightly over 1,000 feet. The error in the location of the leak as calculated from the volume of the nitrogen, called the primary standard, was 17 inches; as calculated from the volume of the tracer gas, called the secondary standard, the error was 17 feet.

Accuracy is of course dependent upon the exactness with which the temperatures and pressures of the gas, and the volumes of the gas spaces, are known, as well as upon the degree to which the manometer is kept balanced during the feeding and column-shifting operations. For the line in question, the exact temperature of the gas within a given section is not known. The temperature used in the computations is the average of the indications determined at the several thermocouple stations. A source of possible further error arises from the fact that the volume of grease used to lubricate the cable is unknown. Nevertheless, the method appears to be a practical means for locating leaks in gas pressure cable lines and similar types of installations. Its disadvantage of being a slow method for locating small leaks is counter-balanced by the fact that interruption of the service of the line is unnecessary.

Discussion

C. T. W. Sutton (Enfield Cables Limited, Brimsdown, Enfield, Middlesex, England): The first pipe line compression cable was installed in 1932 between Hackney and Walthamstow, London for the Central Electricity Board. The installation of a steel pipe containing high gas pressure was a bold venture in those days because little knowledge was available in Britain of methods of testing, welding, and protecting thin steel tubes laid direct in the ground. Unfortunately, on completion a leak was found to exist, due to a flaw in a tube.

To locate this weakness many methods were investigated including pressure measurements, gas detectors, and so forth. Finally success was obtained by a technique employing principles almost identical to those described in the paper although differing in such details as methods of gas analysis and the type of tracer gas used.

During the initial years of service, leaks developed from time to time caused by electrolysis due to stray current from the d-c third rails, all of which were located to within a few feet by using the tracer or bubble method, described in British patent 421,324.

The location of gas leaks on the Hackney-Walthamstow line was rendered more difficult because only one barrier joint, in the middle of the run, had been installed and the joints were not accommodated in manholes but were buried directly in the ground, and no provision had been made for gas testing at the joints. In spite of these drawbacks leaks of varying magnitudes were quickly and accurately found, excavating being necessary at a few joints only. It was found that apart from the measurement of the actual magnitude of the leak, to estimate the gas flow it was unnecessary to measure gas volumes to any great degree of accuracy as the tracer gas acted merely as an indicator of the direction of the main gas flow. In passing, it is of particular interest to note, that since the gas pressure was first applied to the Hackney-Walthamstow line in 1932 it has never once been released, all leak locations, repairs, and recoating have been carried out with full gas pressure maintained, and never once has there been any doubt as to its electrical efficiency. Also, since recovering the pipe with the "Sandwich Protection" no gas leak has occurred for more than four years.

Our method can be described briefly. The line was shut in at both ends and a small volume of tracer gas, either oxygen or air was injected into a joint and left for a waiting period depending on the magnitude of the leak. The next procedure located the position of the tracer by gas sampling at the

injection joint, pushing the whole gas content of the pipe along in a similar manner to that described in the paper and so, by process of elimination, the leak was narrowed down to a length between two adjacent joints. Alternatively, gas was fed in at one end only, to maintain constant pressure in the pipe. The tracer was put into the line at a joint as already described and an analysis of the gas was taken immediately. If the injection joint was between the gas feeding point and the leak the tracer disappeared quickly while on the other hand, if the injection point was beyond the fault, the tracer remained stationary losing its concentration by diffusion only.

The final operations consisted of injecting the tracer into one of the joints after which it was pushed a known distance towards the leak, and left for a period when the location and the shape of the tracer were determined by sampling the moving gas as before. Finally, a volume of the tracer gas was pushed directly over the leak, a condition recorded by the facts that the tracer had remained stationary during the waiting period and a proportion of its volume was lost. An aromatic volatile liquid injected with the last tracer was found to assist greatly during excavations.

The author mentions leaks of the magnitude of 200 cubic feet per day. We have never encountered leaks of this size in actual practice. They have usually been from 20 to 100 cubic feet per day and we would expect to locate a leak of 200 cubic feet per day on the Hackney-Walthamstow line very quickly.

Experience has shown that leaks of less than 20 cubic feet per day cannot be located by the tracer methods because the gas flow in these instances is very slow and the actual movements masked by diffusion.

New methods using artificial barriers and leaks with differential gauges similar to those described in the paper have enabled leaks of the order of 5 cubic feet per day to be found. It was necessary in these tests to allow for temperature variations, wave motion and so forth as given in the paper, but as already stated, measurements to this degree of accuracy were not necessary for the larger losses. Step 3 in the paper would be impracticable for very small leaks of the magnitude mentioned, as a waiting period of days or even weeks would be required for the gas to flow to the leak.

Finally, the tracer or bubble methods do not readily lend themselves to locating gas leaks on self-contained cables, as the large volume of gas in the joints, compared to that in the cable, creates very serious errors and other means have had to be found.

While we can appreciate the work done by the author in preparing the paper, we consider that apart from certain details little has been added to the information on leak detection which has been available for some time. We can only assume by the remarks in the first paragraph that the author had no knowledge of the methods in use in England, Norway, Denmark, and Germany or of the existing British patent 421,324 and others.

Kenneth S. Wyatt (Phelps Dodge Products Corporation, New York, N. Y.): The author's paper is very timely. It will solve the last problem in the minds of many engineers who would like to use gas in pipe cable. The same problem arose in connection with the original pipe cable in London, in 1931. Some of the best engineers in London were at their wits ends trying to develop a method of locating pinhole leaks in the pipe. The solution was due to D. A. O'Duffey, chief chemist of Enfield Cable Works, which basically was similar to that proposed by Piper.

There has been no leakage whatever of gas in the London cable for nearly five years. The electricity authorities there are now so confident of the practicability of complete tightness of 200 pounds per square inch gas systems that they now specify no gas bottles shall be attached permanently to the line. There is merely a simple coupling provided for adding gas should it be needed.

John D. Piper: The author wishes to thank Sutton for his written remarks, particularly because they provided an opportunity to acknowledge publicly the prior and somewhat similar work described in British patent 421,324. As Sutton surmises, the writer was unaware at the time the paper was submitted that such a patent existed. A mimeograph description of a so-called "Enfield" method for locating gas leaks in compression cables was, however, at hand, reading as follows:

The Enfield Cable Works has developed a method which is well suited for locating slow leaks in the pipe line. In this method the cable remains in service during the entire period of leak location and repair. The completed line has a valve on each of the short sections of large diameter pipe which serve as pipe sleeves for the cable joints. In the Enfield method, a so-called bubble of another gas (either air or oxygen) is introduced into the pipe line through the valve on the pipe sleeve of a cable joint at or near the center of the line. Usually about 50 cubic feet (atmospheric pressure) of the foreign gas is injected to form the bubble. The volume of the gas in the pipe line at operating pressure is of the order of one cubic foot at atmospheric pressure per lineal foot of pipe. Consequently the "bubble" occupies approximately a 50-foot length of the pipe line. Owing to the high gas pressure and the very large ratio of the pipe length to pipe diameter, diffusion of the bubble of foreign gas with the nitrogen in the line is very slow. Hence after being introduced into the pipe line, the bubble gradually drifts towards the leak. By taking samples of gas at joints adjoining that at which the foreign gas was introduced, the direction of the leak from the center of the circuit can be determined readily.

Knowing in which half of the line the leak is to be found, the next step is to introduce a bubble near the center of the faulty half and repeat the tests. The same operation is continued until leak is known to be confined to a section between two cable joints.

After the section in which the leak exists is known, a bubble of gas is injected into one of the two joints on each side of the leak. The "bubble" is then pushed toward the leak by introducing a predetermined volume of nitrogen gas at one end of the line and taking out an equal volume of gas at the other end of the line. From the volume of nitrogen gas removed and added, the position of the foreign gas bubble is known with reasonable accuracy.

The procedure is then reversed, and the foreign gas bubble is returned to its initial position. As the bubble is being pushed past its initial position, the operator at the joint takes out samples of gas at intervals. From the foreign gas content of these samples and the length of the bubble, as determined from the volume of nitrogen introduced and removed at the ends, the volume of the returning gas bubble can be found from a simple plot of gas content against bubble length. If the volume of the returning bubble is the same as that originally introduced, the bubble has not passed over the leak.

On the other hand, if the returning bubble is found to have lost part of its initial volume, the bubble has been over the leak and the leak is known to be somewhere in the section of pipe that was occupied by the bubble on its forward trip. The location is then checked by repeating the test from the other joint. Before excavating a phial of ethyl mercaptan is introduced and pushed along the line to the vicinity of the leak. The odor of this gas is helpful in locating the exact spot.

As thusly described the method could not be used for The Detroit Edison Company's gas pressure cable for the following reasons:

1. Neither oxygen nor air could be permitted in the line.
2. It would be impractical to wait until the bubble drifted to an adjacent joint before the direction toward the leak could be ascertained.
3. Location of the position of the leak between two joints by the loss of volume of a bubble placed over the leak would, unless the operators were exceedingly good guessers, require a huge expenditure of man-hours and dry nitrogen.
4. Ethyl mercaptan or any other sufficiently powerful odorant known could not be tolerated in a gas-pressure cable for reasons discussed in this paper.

Accordingly the leak test method, as described in the paper, was devised specifically for the company's cable and was thoroughly tested. During the period of the development, interest in pipe-contained gas pressure cables became very active in this country. The fact that a practical method had been devised for locating gas leaks that might develop in such cables became known, with the result that numerous inquiries were received not only concerning the principles of the method, which are exceedingly simple, but also concerning the field-learned "know-how" of applying these principles which is rather complex. It therefore seemed advisable to make the information available to all concerned.

In preparing the paper for publication, the author recognized that some of the principles were similar to those described in the quoted excerpt concerning the Enfield method, and also that insofar as manometers are used in step 1 the method resembled a method used by the Bell Telephone Company for locating leaks in telephone cables. Inquiry revealed that the method used by Bell Telephone Company had never been published. No record of the Enfield method was found in the technical literature and thus it was assumed that it was unpublished. Resemblances between the two methods seemed too remote to warrant the making of direct inquiry to the Enfield Cable Works.

The author now knows that the principle of step 2 is almost identical with that described in British patent 421,324 and in Sutton's comments. First knowledge of this fact and of the existence of the patent was obtained through the courtesy of Kenneth S. Wyatt who furnished a photostatic copy of part of the patent. From this copy it was learned that the quoted description of the Enfield method was incomplete insofar as it referred to the part to which objection was raised concerning the necessity for the bubble to reach the next joint before its direction of movement could be ascertained.

Although the author is glad to acknowledge that unknown to him the principle of step 2 had been anticipated, he wishes to call attention to the fact that through the use of the techniques and instruments described in the paper the principles may be safely employed in locating leaks in gas pressure cables where oxygen cannot be used. Pure carbon dioxide could possibly be used if it could be obtained commercially in an adequately dry state. This would reduce the requirements for the gas analysis equipment. So far as the author is aware no source of

adequately dry commercial carbon dioxide exists and if it did its solubility in oil might be troublesome. For this reason the low concentrations described and a sensitive analyzer are recommended.

The principle of step 3, although utilizing the principle of slow diffusivity of compressed gases in long slender vessels—a principle which, by the way, anticipates the principle even of British patent 421,324, apparently is sufficiently different from the final test of the Enfield method that anticipation is not claimed. The author believes that both methods have their merits and that which should be selected would depend upon the length and specific volume of the pipe space and the economic justification for seeking a leak of particular size. Descriptions of the final step of the Enfield method, at least those presently available to the writer, are insufficiently specific to enable the author to estimate the number of manhours and volumes of gas that would be required to locate a leak. Sutton is probably right in claiming the Enfield method to be the better for locating a very small leak. The author believes, however, that for leaks having economic significance in pipe-contained cables the method described as step 3 in the paper requires less gas and less manhours, is more precise, and in addition is better adapted to gas pressure cables because nothing injurious to the cable is introduced.

In summary and conclusion, the author regrets that the prior work of which Sutton wrote was not acknowledged in the original paper. Interest in gas pressure cables is mounting rapidly in this country and all utilities who have such cables should be prepared to find leaks should any develop in their systems. Concerning sizes of leaks, The Detroit Edison Company not only has had no leak of 200 cubic feet per day (atmospheric pressure) in the pipe line under discussion but also, except for terminals, has had no leak at all. Nevertheless it is ready to locate leaks should any develop in that line, one under construction, or others contemplated. It is pleased to pass along significant information obtained in order that others may also be prepared, and welcomes any suggestions concerning means by which leak location may be improved. In this connection the author believes that the industry on this side of the ocean would welcome a published article from our friends on the other side giving some of the details of the equipment and techniques involved and experiences with them.

Bibliography of Relay Literature 1944–1946

AN AIEE COMMITTEE REPORT

THIS interim report was prepared by the project committee on relay bibliography of the AIEE relay committee in order to make immediately available this information to the entire industry. Previous to the last published bibliography on this subject, this material had been available only to the membership of the relay committee annually and to the industry at 10-year intervals. However, it was believed by the committee that the publication of such data should be made at 3-year intervals in order to place the information in the hands of all interested parties before such information should become obsolete.

The "Bibliography of Relay Literature, 1927–1939," and the "Bibliography of Relay Literature, 1940–1943," were published in pamphlet form and also in AIEE TRANSACTIONS, volume 60, 1941, pages 1435–47, and volume 63, 1944, October section, pages 705–09, respectively.

The articles listed in this bibliography (1944 to 1946) include all those appearing in the AIEE TRANSACTIONS or ELECTRICAL ENGINEERING as well as most of the chief technical publications of the world from January 1944 through December 1946. The listing of these articles is subdivided into several sections, depending upon the general substance of the article. In each section, the entries are numbered consecutively and listed alphabetically by years, the first significant word of the title determining the alphabetical position. Each article is listed in one section only.

Paper 48-6, recommended by the AIEE relay committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted October 30, 1947; made available for printing November 20, 1947.

This report of the AIEE relay committee, W. R. BROWNLEE, *chairman*, was prepared by a working group of the project committee. Personnel of the working group consists of C. E. PARKS, assistant system operating engineer, power department, Public Service Company of Indiana, Inc., Indianapolis, Ind.; S. GOLDSMITH, operating engineer, Cincinnati Gas and Electric Company, Cincinnati, Ohio; and C. L. SMITH, relay engineer, electric distribution department, Rochester Gas and Electric Corporation, Rochester, N. Y.

1944

1. A NEW CARRIER RELAYING SYSTEM, **T. R. Halman, S. L. Goldsborough, H. W. Lensner, A. F. Drompp.** AIEE TRANSACTIONS, volume 63, 1944, August section, pages 568–72. Discussion, 1944, page 1423.

2. A VERSATILE POWER-LINE-CARRIER SYSTEM, **H. W. Lensner, J. B. Singel.** AIEE TRANSACTIONS, volume 63, 1944, March section, pages 129–32, Discussion, 1944, page 437.

3. FAULT CURRENT POLARITIES COMPARED BY CARRIER, **J. T. Logan.** *Electrical World*, volume 121, April 15, 1944, pages 84–5.

4. ONE CARRIER RELAY FOR "PHASE AND GROUND," **S. C. Leyland.** *Electrical World*, volume 121, May 13, 1944, pages 128, 130.

1945

5. 220 KV. CARRIER CURRENT RELAYING ON PACIFIC GAS AND ELECTRIC COMPANY'S TRANSMISSION SYSTEM, **J. L. Buckley.** *Electrical West* (San Francisco, Calif.), volume 94, May 1945, pages 74–6.

6. PHASE-COMPARISON CARRIER-CURRENT RELAYING, **A. J. McConnell, T. A. Cramer, H. T. Seeley.** AIEE TRANSACTIONS, volume 64, 1945, December section, pages 825–32. Discussion, 1945, pages 973–5.

7. TRANSMISSION LINE PROTECTION USING SUPERIMPOSED CARRIER SIGNALLING, **D. H. Towers, H. McDonald.** *Electrical Review* (London, England), volume 137, July 20, 1945, pages 95–100.

1946

8. PROTECTION OF PILOT WIRES FROM INDUCED POTENTIALS, **R. B. Killen, G. G. Law.** AIEE TRANSACTIONS, volume 65, May 1946, pages 267–70.

9. SOME RECENT DEVELOPMENTS IN THE PROTECTION OF E.H.V. OVERHEAD-LINE NETWORKS, **H. Leyburn, C. H. Lackey.** Conference Internationale des Grands Réseaux Electriques à Haute Tension (Paris meeting), June 27–July 6, 1946. Paper 338, pages 1–26.

Section C. Line Protection—Ground Faults

1944

1. MODERN EARTH FAULT RELAY EQUIPMENT FOR USE ON SYSTEMS PROTECTED BY PETERSEN COILS, **L. B. S. Golds, C. L. Lipman.** *Electrician* (London, England), volume 132, February 25, 1944, pages 169–170; discussion, page 170. Also, *Journal*, Institution of Electrical Engineers, volume 91,

part 2, 1944, October section, pages 377–88; discussion, pages 389–96.

2. The Functions of Ground Preference in Carrier-Current Relay Schemes, **S. C. Leyland, S. L. Goldsborough.** AIEE Transactions, volume 63, 1944, March section, pages 97–9. Discussion, 1944, page 437.

3. Wattmeter Relay Protection: Isolation and Indication of Earth Faults, **L. B. S. Golds, C. L. Lipman.** *Electrical Review* (London, England), volume 134, February 18, 1944, page 234.

1945

4. Improvised Relay For Low Volt-Ampere Use, **A. R. Constant, Jr., M. H. Sykes.** *Electrical World*, volume 124, October 27, 1945, page 122.

5. Lockout Relays Deter Possible Outages, **A. R. Curry.** *Electrical World*, volume 123, March 3, 1945, page 76.

6. The How and Why of Ground Fault Protection, **J. L. Blackburn.** *Electric Light and Power* (Chicago, Ill.), volume 23, November 1945, pages 58–63.

1946

7. Neutral-Displacement Protection: New Type of Relay, **E. A. Burton.** *Electrical Review* (London, England), volume 139, December 20, 1946, pages 1012–1015.

8. Operating Experience With Distance Ground Relays, **W. A. Wolfe.** AIEE Transactions, volume 65, July 1946, pages 458–62. Discussion, 1946, pages 1185–7.

9. Sensitive Ground Relay Protection For Complex Distribution Circuits, **L. F. Hunt.** AIEE Transactions, volume 65, November 1946, pages 765–8. Discussion, 1946, pages 1180–1.

Section D. Line Protection—General

1945

1. Excess-Current Protection by Overcurrent Relays on Medium Voltage Circuits, **A. G. Shreeve, P. J. Shipton.** *Journal*, Institution of Electrical Engineers (London, England), volume 92, October 1945, pages 430–41; discussion, pages 441–50.

1946

2. New Devices For Rapid Selective Protection of H. T. Transformer Stations and Major Distributing Substations at Medium Voltage, **C. Ramelot.** Conference Internationale des Grands Réseaux Electriques à Haute Tension (Paris meeting), June 27–July 6, 1946. Paper 309, pages 1–12.

3. Overload Protection, **E. V. C. Habgood.** *Electrical Review* (London, England), volume 139, September 13, 1946, pages 416–18.

Section E. Bus Protection

1945

1. Distance-Relay Protection For Sectionalized Bus, **C. A. Molsberry.** *Electrical World* volume 124, August 18, 1945, pages 96–8.

1946

2. Busbar Zone Protection, **G. W. B. Mitchell.** Conference Internationale des Grands Réseaux Electriques à Haute Tension (Paris meeting), June 27–July 6, 1946. Paper 340, pages 1–12.

3. Linear Couplers—Field Tests and Experience at York and Middletown, Pa., **E. L. Harder, E. H. Klemmer, R. E. Neidig.** AIEE Transactions, volume 65, 1946, March section, pages 107–113.

4. Southwork Station—Aimed to be Simple and Reliable, **L. R. Gaty, E. B. Shew.** *Electrical World*, volume 126, July 20, 1946, pages 73–75.

Section F. Apparatus Protection

1944

1. An Automatic Watchman For Air-Cooled Transformers, **E. W. Tipton.** *Westinghouse Engineer* (Pittsburgh, Pa.), volume 4, November 1944, pages 187–9.

2. Differential Generator Control Relay For D-C Aircraft Electric Systems, **F. E. Crever.** AIEE Transactions, volume 63, 1944, August section, pages 589–92.

3. Differential Protection of Generator-Transformer Unit, **A. H. Burkhalter.** *Electrical World*, volume 122, August 5, 1944, pages 87–89.

4. Grounding Switch Protects Transformer Installed Near Center of 50-Mile Line. *Electrical World*, volume 121, March 4, 1944, page 58.

5. Relay For Air-Cooled Type Transformers, **E. W. Tipton.** *Electrical World*, volume 122, July 8, 1944, pages 116, 118.

6. Selection of Thermal Overload Motor Protection, **C. W. Kuhn.** *Electrical World*, volume 121, April 1, 1944, pages 61–3.

7. Short-Circuit Switch in Lieu of Breaker, **J. F. Sinnot.** *Electrical World*, volume 121, April 29, 1944, pages 50–51.

8. Thermal Protection of Transformers Under Overload Conditions, **V. M. Montsinger, G. Camilli.** AIEE Transactions, volume 63, April section, pages 160–4. Discussion, 1944, page 444.

9. Transformer Magnetizing Inrush Currents and Influence on System Operation, **L. F. Blume, G. Camilli, S. B. Barnham, H. A. Peterson.** AIEE Transactions, volume 63, 1944, pages 366–74. Discussion, page 423.

10. Turbine-Generator Field Current Relay, **P. H. Adams.** *Electrical World*, volume 121, June 24, 1944, pages 58–9.

11. Vibration Protection For Rotating Machinery, **R. L. Webb, C. S. Murray.** AIEE Transactions, volume 63, 1944, July section, pages 534–7.

1945

12. Generator Protected By a "Floating" C. T., **E. G. Ratz.** *Electrical World*, volume 124, August 18, 1945, pages 115–6.

13. Induction Motor Protection; Development of a New Type of Relay, **D. E. Bird, L. B. S. Golds.** *Electrical Review* (London, England), volume 137, July 13, 1945, pages 60–2.

14. Rectifier Relay For Transformer Protection, **E. L. Michelson.** AIEE Transactions, volume 64, 1945, May Section, pages 252–4.

15. Rectifier Relay Improves Transformer Protection, **E. L. Michelson.** *Electric Light and Power*, volume 23, March 1945, pages 70–3.

16. Relay in Sealing Circuit Protects Stalled Motor, **W. C. Noddings.** *Electrical World*, volume 123, June 9, 1945, page 124.

17. The New Limitherm Relay, **O. Nsef, T. Imhof.** *Engineer's Digest* B. D. Publications, Inc., volume 2, August 1945, pages 378–9.

18. Transformer Protection; Differential Circulating Current Principle, **H. E. Forrest.** *Electrical Review* (London, England), volume 136, January 5, 1945, pages 23–6.

19. Transformer Protection; New Instantaneous Magnetic Balance System, *Electrical Review* (London, England), volume 137, November 16, 1945, pages 711–12.

1946

20. Automatic Control of Large Synchronous Condensers, **M. J. Brown.** AIEE Transactions, volume 65, 1946, August–September section, pages 609–16.

21. Differential Protection, Delta-Wye Transformer Banks, **J. M. De Guilmo.** *Electrical World*, volume 126, August 3, 1946, page 74; August 17, 1946, page 89; August 31, 1946, pages 74, 76; September 14, 1946, pages 114, 117.

22. Differential Relay Protection Extended To Tertiary Winding, **J. R. Linders.** *Electrical World*, volume 126, October 12, 1946, page 100.

23. Motoring Protection For A-C Generators, **L. L. Fountain.** *Westinghouse Engineer*, volume 6, November 1946, pages 190–1.

24. Protection of Powerhouse Auxiliaries, report by the working group of the AIEE relay subcommittee. AIEE Transactions, volume 65, November 1946, pages 746–50. Discussion, 1946, pages 1115–16.

Section G. Distribution and Network Protection

1944

1. Protective Systems For Supply Network Operating At Voltages Up To 11 Kv, O. Howarth. *Journal*, Institution of Electrical Engineers (London, England), volume 91, part 2, February section, 1944, pages 6–10.

2. Short Cuts In Relay-Fuse Co-ordination, **C. H. Summers.** *Electric Light and Power*, volume 22, June 1944, pages 84–90.

1945

3. Electric Power in a Steel Plant, **R. W. Graham.** AIEE Transactions, volume 64, 1945, December section, pages 816–18. Discussion, 1945, pages 994–5.

1946

4. Network Equipment Goes Overhead For Economy, **Harold Cole.** *Electric Light and Power*, volume 24, June 1946, pages 84–92.

Section H. Service Restoration

1944

1. Automatic Throwover Without Oil Switches, **L. M. Robertson.** *Electrical World*, volume 122, August 5, 1944, pages 108, 112.

2. Hi-Voltage Interconnections Made Reliable By Single Pole Switching, **J. J. Trainor, H. N. Muller, Jr.** *Power Plant Engineering* (Chicago, Ill.), volume 48, June 1944, pages 77–9.

3. High-Voltage Oil Circuit Breakers For Rapid Reclosing Duty, **A. W. Hill, W. M. Leeds.** AIEE Transactions, volume 63, 1944, March section, pages 113–18. Discussion, 1944, page 452.

4. Pros and Cons of Fast Reclosure of Transmission, **H. R. Vaughan.** *Electrical World*, volume 122, December 23, 1944, pages 66–8.

1945

5. Automatic Line Transfer For Suburban Substation, **H. F. Beique.** *Electrical World* volume 123, May 12, 1945, page 132.

6. Nine Years' Experience With Ultrahigh-Speed Reclosing of High-Voltage Transmission Lines, **Philip Sporn, C. A. Muller.** AIEE Transactions, volume 64, 1945, May section, pages 225–8. Discussion, 1945, page 445.

7. Reclosing Single-Circuit Tie Lines, **H. N. Muller, Jr., W. W. Parker.** *Westinghouse Engineer*, volume 5, March 1945, pages 60–3.

1946

8. A New Electronic Timing Relay For Reducing Outages on Power Circuits, **Frank S.**

Dioubs. AIEE TRANSACTIONS, volume 65, July 1946, pages 407–11.

Section I. General and Miscellaneous Relaying

1944

1. A NEW FREQUENCY RELAY FOR POWER-SYSTEM APPLICATIONS, **H. J. Carlin, J. L. Blackburn.** AIEE TRANSACTIONS, volume 63, 1944, August section, pages 553–7. Discussion, 1944, page 1421.

2. BIBLIOGRAPHY OF RELAY LITERATURE 1940–1943, **AIEE Relay Subcommittee.** AIEE TRANSACTIONS, volume 63, 1944, October section, pages 705–09.

3. ELECTRIC CIRCUIT FAULT-PROTECTIVE PRINCIPLES AS APPLIED TO D-C AIRCRAFT SYSTEMS, **R. H. Kaufmann.** AIEE TRANSACTIONS, volume 63, 1944, pages 333–344. Discussion, page 482.

4. FAULT PROTECTION, **E. H. Beckert.** *General Electric Review* (Schenectady, N. Y.), volume 47, December 1944, pages 22–3.

5. MODIFIED TRIPPING REDUCES O.C.B. DUTY, **R. C. R. Schulze.** *Electrical World*, volume 121, March 4, 1944, page 94.

6. PRINCIPLES OF SYSTEM RELAYING. Report of the electrical equipment committee of the Edison Electric Institute. *Publication M-3*, July 1945.

7. PROTECTIVE SYSTEMS, **D. C. Field** and others. *Journal*, Institution of Electrical Engineers (London, England), volume 91, part 2, 1944, February section, pages 2–27; discussion, pages 27–34.

8. 99.47% RELAY PERFORMANCE AIDS WAR EFFORT, **B. M. Jones, W. M. Evans.** *Electric Light and Power*, volume 22, October 1944, pages 66–70.

1945

9. "E" FOR EXCELLENT RELAY PERFORMANCE, **A. F. Ayres.** *Electrical World*, volume 123, March 3, 1945, page 104.

1946

10. CASCADE OPERATION PROTECTS WEAK BREAKERS, **M. P. Osburn.** *Electric Light and Power*, volume 24, March 1946, pages 70–1.

11. ELECTRONIC RELAYS, **W. D. Macgeorge.** *Electrical World*, volume 126, July 20, 1946, pages 87–8; August 3, 1946, page 75; August 17, 1946, pages 87–8; August 31, 1946, pages 71–2.

12. INSTANTANEOUS TRIP BLOCKING ON A-C SUPPLY, **Oliver Ramsaur.** *Electrical World*, volume 125, June 22, 1946, page 114.

13. PHILOSOPHY OF RELAYING, **E. W. Knapp, B. C. Hicks.** AIEE TRANSACTIONS, volume 65, November 1946, pages 735–40. Discussion, 1946, page 1135.

14. QUICK-TRIP BUS TIES REDUCE BREAKER DUTIES. *Electrical World*, volume 125, May 11, 1946, page 95.

15. SIMPLICITY IN PROTECTIVE RELAYING, **Lloyd F. Hunt.** AIEE TRANSACTIONS, volume 65, 1946, pages 995–9. Discussion, 1946, pages 1121–3.

16. SLOW-ACTING RELAYS, **A. B. Smith, H. N. Wagar, A. W. Vincent, E. E. George.** ELECTRICAL ENGINEERING, volume 65, December 1946, pages 557–63.

Section J. Testing and Analyzing

1944

1. FIELD TEST KIT FOR A. C. NETWORK RELAYS, **W. B. Rice.** *Electrical World*, volume 122, September 16, 1944, pages 100, 102.

2. MINIATURE OSCILLOGRAPH, **G. H. Hupman.** *General Electric Review*, volume 47, December 1944, pages 53–7.

3. RELAY TEST SET: AUTOMATIC TIMING FOR SECONDARY INJECTION OF SUBSTATION RELAYS, **G. A. Thompson.** *Electrical Review* (London, England), volume 134, June 2, 1944, pages 775–6.

4. SYSTEM TEST CHECKS RELAY OPERATIONS **C. A. Hummel, H. E. Chambers.** *Electrical World* volume 122, September 30, 1944, pages 96, 98.

5. TANK DEVELOPS LONG OSCILLOGRAPH FILMS, **A. A. Miller.** *Electrical World*, volume 122, December 9, 1944, page 120.

1945

6. CYCLE RECORDING DEVICE FOR TIMING HIGH-SPEED RELAYS, **C. W. Cogburn.** *Electrical World*, volume 123, April 14, 1945, page 136.

7. DIRECTIONAL RELAYS; CHECKING CONNECTIONS FOR RING MAIN AND PARALLEL-FEEDER INSTALLATIONS, **V. B. Shah.** *Electrical Review* (London, England), volume 137, October 26, 1945, pages 601–3.

8. FAULT CURRENT-DISTANCE CURVES HELP LOCATE TRANSMISSION TROUBLE, **C. S. Roadhouse, O. R. Hanila.** *Electrical World*, volume 123, March 31, 1945, pages 60–1.

9. FAULTS OF THREE SYSTEMS ON A SINGLE OSCILLOGRAPH, **G. Steeb.** *Electrical World*, volume 123, April 28, 1945, page 99.

10. FIELD TEST YIELDS RATIO OF DELTA-CONNECTED BUSHING C. T., **C. E. Asbury.** *Electrical World*, volume 124, November 24, 1945, pages 72–5.

11. FOUR USES OF A MULTIMETER IN RELAY TESTING, **H. L. Goodridge.** *Electrical World*, volume 123, April 14, 1945, page 130.

12. INHERENT ERRORS IN THE DETERMINATION OF SYNCHRONOUS-MACHINE REACTANCES BY TEST, **C. Concordia, F. J. Maginniss.** AIEE TRANSACTIONS, volume 64, 1945, June section, pages 288–94. Discussion, 1945, page 491.

13. MEASUREMENT OF THE SUBTRANSIENT IMPEDANCES OF SYNCHRONOUS MACHINES, **G. F. Tracy, W. F. Tice.** AIEE TRANSACTIONS, volume 64, 1945, February section, pages 70–5. Discussion, 1945, page 429.

14. OSCILLOGRAMS FILED IN COMPACT CABINET, **G. Steeb.** *Electrical World*, volume 123, February 17, 1945, page 118.

15. PORTABLE TRANSFORMER FOR RELAY TESTS, **J. P. Dawson.** *Electrical World*, volume 123, April 14, 1945, page 123.

16. VERSATILE DESIGN OF RELAY TEST BOX, **J. F. Carolus.** *Electrical World*, volume 124, August 4, 1945, page 124.

1946

17. AN AUTOMATIC OSCILLOGRAPH WITH A MEMORY, **A. M. Zarem.** AIEE TRANSACTIONS, volume 65, March 1946, pages 150–4. Discussion, 1946, page 514.

18. FAULT CURRENT MEASURING DEVICE, **M. J. Lantz.** AIEE TRANSACTIONS, volume 65, 1946, December section, pages 839–43.

19. FAULT LOCATION AND RELAY PERFORMANCE ANALYSIS BY AUTOMATIC OSCILLOGRAPHS, **H. P. Dupuis, W. E. Jacobs.** AIEE TRANSACTIONS, volume 65, July 1946, pages 442–6. Discussion, 1946, pages 1125–6.

20. INDUCTION RELAY TESTING, **C. G. Rumsam.** *Electrical Review* (London, England), volume 138, May 31, 1946, pages 841–3.

21. RELAY TESTING, **W. M. Gore.** *Electrical Review* (London, England), volume 138, February 22, 1946, pages 293–5.

22. SIMPLE NETWORK ANALYZER MODIFIED FOR COUPLED FAULTS, **M. J. Lantz.** *Electrical World*, volume 125, April 13, 1946, pages 108–09.

Section K. System Stability

1944

1. CAPACITORS, CONDENSERS, AND SYSTEM STABILITY, **J. W. Butler, T. W. Schroeder, W. Ridgeway.** AIEE TRANSACTIONS, volume 63, 1944 pages 1130–8. Discussion, page 1378.

2. RECLOSING OF SINGLE TIE LINES BETWEEN SYSTEMS, **W. W. Parker, H. A. Travers.** AIEE TRANSACTIONS, volume 63, 1944, pages 119–22 Discussion, 1944, page 470.

3. SINGLE-POLE RECLOSURE HOLDS STABILITY AND STRESSES, **W. A. Datt.** *Electrical World*, volume 122, September 30, 1944, pages 68–9.

1945

4. IMPROVING STABILITY BY RAPID CLOSING OF BUS-TIE SWITCHES, **E. W. Kimbark.** AIEE TRANSACTIONS, volume 64, 1945, February section, pages 61–4. Discussion, 1945, page 456.

1946

5. CHARACTERISTICS OF A 400-MILE 230-KV SERIES-CAPACITOR-COMPENSATED TRANSMISSION SYSTEM, **B. V. Hoard.** AIEE TRANSACTIONS, volume 65, 1946, pages 1102–14. Discussion, 1946, pages 1178–80.

6. NOTES ON RUNNING OUT OF STEP, **P. Henriet.** Conference Internationale des Grands Réseaux Electriques à Haute Tension (Paris meeting), June 27–July 6, 1946. Paper 335, pages 1–17.

7. SINGLE-POLE SWITCHING PROVES BEST FOR 66 KV INTERCONNECTION, **C. M. Lytle, J. S. Palmer.** *Electric Light and Power*, volume 24, August 1946, pages 54–7.

8. SLIP CYCLE RELAYS AUTOMATICALLY SEPARATE POWER SYSTEMS, **L. F. Hunt.** *Electrical World*, volume 126, September 14, 1946, page 97.

9. STABILITY LIMITS OF LONG TRANSMISSION LINES, **Ivar Herlitz.** Conference Internationale des Grands Réseaux Electriques à Haute Tension (Paris meeting), June 27–July 6, 1946. Paper 307, pages 1–31.

10. STABILITY PROBLEMS ON INTERCONNECTED POWER SYSTEMS IN THE PROVINCE OF QUEBEC, CANADA, **John Morse.** Conference Internationale des Grands Réseaux Electriques à Haute Tension (Paris meeting), June 27–July 6, 1946. Paper 303, pages 1–22.

11. ULTRA-HIGH SPEED RECLOSING DEMONSTRATES ITS VALUE, **Philip Sporn, J. H. Kinghorn.** Conference Internationale des Grands Réseaux Electriques à Haute Tension (Paris meeting), June 27–July 6, 1946. Paper 106, pages 1–12.

Section L. Methods of Calculation

1944

1. EVALUATING IMPEDANCE OF ZIG-ZAG TRANSFORMERS, **S. L. Foster.** *Electric Light and Power*, volume 22, February 1944, pages 54–6, 78.

2. IMPEDANCE CIRCLE DIAGRAMS, **H. L. Stewart.** *General Electric Review*, volume 47, August 1944, pages 20–5.

3. NOVEL SLIDE RULE USED FOR RELAY SETTING. *Electrical World*, volume 122, August 5, 1944, pages 120, 124.

4. PHASE SEQUENCE AND SWITCHGEAR DEVICES, **A. D. Shelley.** *General Electric Review*, volume 47, September 1944, pages 19–22.

5. REVISIONS MADE TO "SIMPLIFIED CALCULATION OF FAULT CURRENTS," **AIEE Protective Devices Committee.** ELECTRICAL ENGINEERING, volume 63, February 1944, page 65.

6. SYMMETRICAL COMPONENTS, **P. W. Ahlquist.** Study of symmetrical components by means of oscillograms. *General Electric Review*, volume 47, October 1944, pages 22–7.

7. SYMMETRICAL-COMPONENTS ANALYSIS OF THE FOUR-PHASE SYSTEM, **A. Boyajian.** AIEE TRANSACTIONS, volume 63, 1944, February section, pages 40–51. Discussion, 1944, page 427.

8. SYSTEM VOLTAGES AND FAULT CURRENTS DETERMINED EASILY ON D-C BOARD, **C. E. Asbury.** AIEE TRANSACTIONS, volume 63, 1944, April section, pages 184–8. Discussion, 1944, page 439.

9. "What Is This Asymmetrical Current and Why Do We Bother With It?" **E. H. Beckert.** *Power Plant Engineering*, volume 48, January 1944, page 65.

1945

10. Dual A-C Network Calculator, **W. W. Parker.** Electrical Engineering, volume 64, May 1945, pages 182–3.

11. Graphical Method of Calculating Fault Currents on a Rural Distribution System, **F. W. Linder.** AIEE Transactions, volume 64, 1945, January section, pages 16–19. Discussion, 1945, page 446.

12. Grounding Principles and Practice, **R. Rudenberg, Claude Jensen, A. A. Johnson, W. R. Bullard, Robin Beach.** Electrical Engineering, volume 64, January 1945, pages 1–13; February 1945, pages 68–74; March 1945, pages 92–9; April 1945, pages 145–51; May 1945, pages 184–94.

13. New Transmission-Line Diagrams, **A. C. Schwager, P. Y. Wang.** AIEE Transactions, volume 64, 1945, September section, pages 610–15. Discussion, 1945, page 955.

14. Symmetrical Components; Their Use in Connection With Transformers, **E. Holzer.** *Electrical Review* (London), volume 136, February 23, 1945, page 136.

15. Two-Phase Co-Ordinates of a Four-Phase Network, **Edward W. Kimbark.** AIEE Transactions, volume 64, 1945, January section, pages 7–9.

1946

16. Determination of Ground Fault Current and Voltages on Transmission Systems, **E. M. Hunter, P. H. Light.** *General Electric Review*, volume 49, April 1946, pages 19–23.

17. Simplified Short-Circuit Analysis For Small Electrical Systems, **J. L. King.** *Power* (New York, N. Y.), volume 90, May 1946, pages 300–03.

Section M. Instrument Transformers and Other Auxiliary Devices

1944

1. Current Transformer Output and Application Charts, **R. Keller.** AIEE Transactions, volume 63, 1944, August section, pages 573–7. Discussion, 1944, page 1422.

2. Field Determination of Current-Transformer Errors By Secondary-Voltage Method, **E. C. Goodale, J. I. Holbeck.** AIEE Transactions, volume 63, 1944, December section, pages 879–82. Discussion, 1944, page 1467.

3. How To Select Tap on Bushing C. T., **F. A. Olmsted.** *Electrical World*, volume 121, May 13, 1944, page 112.

4. Now Instrument Transformer Standards Make Sense, **F. E. Davis.** *Allis-Chalmers Electrical Review* (Milwaukee, Wis.), volume 9, June 1944, pages 5–11.

Use of Reduced-Scale Models for the Solutions of Cable Temperature Problems—II

ANDREW GEMANT
NONMEMBER AIEE

JOSEPH STICHER
MEMBER AIEE

IN a previous paper[1] the authors showed that a reduced-scale cable installation can be used for the determination of cable temperatures. In that paper, first the theoretical basis of the scale reduction was given; next, certain tests were described to show that the method, as carried out in the laboratory, yields results that agree satisfactorily with results of a rigorous computation or with field data. Such a model installation may be looked upon as a novel laboratory tool, and the question arose in what practical cases this tool might be used to advantage. In the following pages a few tests are described to show some of these cases. The list is not meant to be exhaustive; it is to be hoped that, as the method becomes more familiar to other workers in this field, new uses will be considered and developed.

Check of Calculations

In the previous paper[1] it was pointed out that a rigorous calculation of temperatures of cables in ducts is not possible. There is, however, the possibility of carrying out calculations based on certain formulas and empirical constants. The basic idea of such a computation, which in the course of years has been improved in various ways, is described by Simmons[2] among others. The calculation is based on the thermal "Ohm's law," the total thermal resistance being divided into three lumped elements connected in series. The formula holds, strictly speaking, only for steady-state conditions, and transient cases are calculated by means of the so-called loss factor which, in its turn, is a function of the load factor. Conversion graphs for the evaluation of loss factors from load factors as well as other pertinent constants, including duct heating constants, have been established by the National Electric Light Association and the Insulated Power Cable Engineers Association.[3] It is worth noting that the cable temperatures calculated from formulas of this kind are usually quite close to reality; this is surprising in a sense if one considers that computation of transient conditions is based on the steady-state equation.

Figure 1. Diagram showing location of eight cables in duct

In practical instances it might be desirable for various reasons that a check of temperature data obtained from such formulas be made by means of another method. The model cable equipment is believed to be well suited for the purposes of such a check. Four tests of this kind are described in this section.

A standard three-by-four duct bank[1] was used in all tests covered by this paper. The bank contained eight 3-conductor 24-kv round shielded cables; the model cables (linear reduction factor equals 4.6) were furnished through the courtesy of the Okonite-Callender Cable Company. The location and designation of the eight cables are shown in Figure 1.

The reproduction in the model of moisture conditions in the field is of considerable importance. The moisture content of the soil as well as the wetness of the ducts usually varies along the length of a cable line. Concerning the former, it is perhaps best to use in the model a degree of moisture that corresponds to an average, representative moisture of the soil in which the field installation in question is located.* That was the procedure followed in our tests. With regard to the wetness of ducts, on the other hand, it is perhaps better to vary the conditions of ducts in the model. This may be done in a single test by keeping some arbitrarily selected ducts dry and others carrying the same load, wet; or else, in a duplicate run, keeping certain selected ducts dry in one run and wet in the other. A wet duct, as the term is used in this investigation on a model installation, is one containing 50 cubic centimeters of water; this amount ensures a conducting path between cable and duct.[1] It corresponds to 4 cubic inches per foot in the field. A dry duct contains no liquid water. In this manner both extreme conditions are covered and the cable operating personnel may select the values that, to their judgment, corre-

Paper 48-7, recommended by the AIEE insulated conductor committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted September 8, 1947; made available for printing November 24, 1947.

ANDREW GEMANT and JOSEPH STICHER are both with the research department of The Detroit Edison Company, Detroit, Mich.

* The soil was a yellow clay, containing about 15 per cent water.

Planned field schedule

spond to the actual conditions of the line, or, if they wish to be conservative, select the higher model temperatures as obtained in dry ducts. In the majority of tests to be presented this procedure was adopted. We shall come back to the question of dry versus wet ducts in more detail in a separate section of this paper.

A description follows of the four tests mentioned.

The first test was designed to reproduce conditions obtaining in a particular duct bank of The Detroit Edison Company for a period of one week in January 1946. The maximum temperatures obtained for a particular day are summarized in Table I. There are three sets of data: one based on measured sheath temperatures in the field, a second computed from loads, and a third from the model equipment.

The computations mentioned herein were carried out by the cable corrosion and loading division of our company; the authors are indebted to W. D. Sanderson for these data. The method of calculation employed is essentially that recommended by IPCEA[3] with the following revisions. The thermal resistance between the sheath and duct wall is determined by Kirke's[3] method. Variable or emergency loads are considered by applying an attainment factor or time constant according to Kirke and Walsh.[3] The thermal resistance between the duct wall and ambient sink is varied according to local conditions existing in the field; the respective constants were obtained by many years of field experience. The details of this computation, which involves many steps, and is based on standard methods, are not reproduced in this connection.

The linear reduction factor used in the model being 4.6, the time reduction factor is $4.6^2 = 21.2$, hence the week's schedule was reproduced in 8 hours; altogether, with 1 hour preheating period in 9 hours. The check of computed data by means of the model, excepting perhaps the cables carrying very low loads, is close.

The second test refers to a load schedule carried out in the field a week in August 1946. The loads in this test were somewhat higher than in the previous test. The temperature data obtained from the model for cables 5 and 9 are shown, together with the corresponding loads, in Figure 2. It may be seen that the temperature versus time curves are reproduced in all detail; the slight time lags between load and temperature curves are also visible. In this test two ducts, pertaining to cables 3 and 11, were dry, the other six wet. Maximum temperatures obtained for a particular day are summarized in Table II.

As may be seen, field data for the sheath are higher (on the average by 6 degrees centigrade) than model data obtained from wet ducts; and equal to or lower than model data from dry ducts. From this it follows that the condition of the ducts in the field was between dry and completely wet, as previously defined. Computed conductor-sheath differentials check fairly well with model data; computed data appear to lie on the safe side.

A third test of this type refers to a weekly load schedule not actually carried in the field, only contemplated. It involved drops in the load of half-hour duration at noontime, and the question was to what extent these drops would affect the

13	Wet	230	45.9	38.0	8.8	7.5
15	Wet	230	43.5	39.0	8.8	6.0

afternoon temperatures. While calculation according to the scheme as mentioned was carried out for this case, too, the temperatures are so far from steady-state values that a check by means of the model seemed advisable. In this test cables 3 and 11 were lying in dry ducts, the other six in wet ducts. Cables 9 to 15 carried the same, rather heavy load, the other cables carried lighter loads. Figure 3 shows load and temperatures for cable 13 (conductor and sheath); the influence of the half-hour load drops on afternoon temperatures is clearly visible. Computed and model data are summarized in Table III. It may be seen that computed data, particularly those for the conductor, agree closely with model data obtained from wet ducts.

A last test in this group refers to an arbitrary load schedule shown by the lower curve of Figure 4. All eight cables carried the same load, the load factor being 85 per cent. In this test all ducts were wet. From standard tables[2] the maximum load for round, shielded, 350,000-circular mil 24-kv cables, eight cables in duct bank, 85 per cent load factor, and 18 C, is 253 amperes. The question was: What permitted load can be derived from a corresponding model test?

The temperatures for cable 13 are shown in Figure 4. As can be seen, the load was made to decrease from day to day (1 day in the field = 68 minutes on the model) according to an arbitrary schedule. The maximum copper temperature for the second day is seen to be 85 C and for the third day 72 C. Taking 77 C as the allowable maximum temperature,[2] the maximum permissible load is determined by interpolation. The maximum load on the second day being 270 amperes, that on the third day 230 amperes, the allowable maximum is 246 amperes. This checks fairly well with the figure obtained from the standard table.

In this connection calculation of duct heating constants from model data and comparison with established values[2] might be of interest. A load schedule, to be discussed in the following sections, served as basis for the calculation, according to the formula

$$C_D = T_{dg}/8LH$$

(C_D = duct constant, T_{dg} = duct to ground temperature differential, L = 24 hour-loss factor, H = heat dissipated in watts per foot of cable). Table IV gives the data. The average for the duct constant for 8 equally loaded cables is 0.64, as compared with 0.77 as given by NELA.[2] A relatively low ground resistivity in the model, about 70 ohms, probably accounts for the difference.

Moisture Condition of Duct

A question that can be easily investigated in the model installation is the effect of the moisture condition of a duct upon cable temperatures. As mentioned in the foregoing section, ducts were kept either in a dry or a wet condition. The dryer a duct is, the greater is the relative role of radiation in the total heat transfer from the cable sheath to the duct wall. The model is strictly applicable for heat transfer by conduction.[1] While in a wet duct the error introduced by radiation is small; it is probably appreciable in a dry duct. It was advisable, therefore, to establish a correction formula which is valid for any degree of wetness. The application of this formula, the derivation of which follows, requires the knowledge of the duct wall temperature which can be measured in the model by means of a thermocouple, introduced into the duct or preferably built into the duct wall during construction. The correction formula to be derived is approximate in that it is strictly valid only for equilibrium conditions.

In the following, H denotes the heat generated per unit length and unit time, T_s sheath temperature, and T_d duct wall temperature as obtained in the model. We then have the following equation for

Figure 4. (left). Loads and temperatures (conductor and sheath) for cable 13

Daily load cycles of varying magnitude

Figure 5. Temperature (conductor and sheath) for cable 3 for dry and wet duct conditions

equilibrium conditions between temperature and heat flow:

$$H=A(T_s-T_d)+B(T_s^4-T_d^4) \quad (1)$$

in which A is the thermal conductance between sheath and duct (varying with amount of water present) and B the radiation conductance, both per unit length. The constants A and B refer specifically to the model. B is known[4] to be

$$B=2\pi\sigma a/[1/\epsilon_d+a/a_d(1/\epsilon_s-1)] \quad (2)$$

with $\sigma=5.7\times10^{-8}$ abs units, a = radius of sheath, a_d = radius of duct, ϵ_d and ϵ_s = emissivities of duct and sheath (0.93 and 0.56, respectively). With $a=0.87$ centimeter and $a_d=1.11$ centimeter, B is 1.85×10^{-4} abs units, or 0.56×10^{-9} if H is measured in watts per foot.

We now introduce the scale-reduction factor q (4.6 in our installation) and write the equation, corresponding to equation 1, as valid for the field. H in the field is by disposition the same as in the model, and so is A by theory, if the degree of wetness is identical in the field and model installations, that is, the amount of water in the field is q^2 times that in the model. Furthermore, T_d in the field and in the model are identical because the heat resistances from duct wall to ambient are by theory the same, and the heat flow H is the same, as just mentioned. Instead of B, however, we have qB because of the factor a in equation 2, and for T_s we write T_x. Thus:

$$H=A(T_x-T_d)+qB(T_x^4-T_d^4) \quad (3)$$

If (T_s-T_d) is small compared with an average duct space temperature T_a, the last brackets in equations 1 and 3 may be simplified:

$$H=A(T_s-T_d)+4BT_a^3(T_s-T_d) \quad (4)$$

$$H=A(T_x-T_d)+4qBT_a^3(T_x-T_d) \quad (5)$$

in which two equations T_a is considered in first approximation as a constant, a representative value being 50°C = 323 K. Equations 4 and 5 represent two equations with two unknown quantities A and T_x, so that T_x, after A is eliminated, can be computed. If we denote T_s-T_d by T_{sd} and T_s-T_x by T_{cor}, then a simple calculation gives the correction T_{cor}:

$$T_{cor}=T_{sd}-H/[(H/T_{sd})+4(q-1)BT_a^3] \quad (6)$$

With $q=4.6$, $B=0.56\times10^{-9}$, and $T_a=323$, we have finally:

$$T_{cor}=T_{sd}-H/[(H/T_{sd})+0.27] \quad (7)$$

As an example, let us take data obtained at $H=11.8$ watts per foot. In a wet duct T_{sd} was 8 C; hence the correction term from equation 7 is 1.2 C. By this amount the sheath (and conductor) temperature in the field is less than in the model. As can be seen, this term is within the accuracy of the method. In a dry duct, on the other hand, T_{sd} was 22 C, hence T_{cor} from equation 7 is 7.4 C. For dry ducts the correction term is no longer negligible. Equation 7 was used in connection with all data in this investigation obtained from dry ducts, and the values as presented are all corrected data.

In order to show the difference in cable temperatures from dry and wet ducts, a particular load schedule, involving 125-ampere overloads of varying duration above a level of 250 amperes, was applied to the eight cables shown in Figure 1. In one test all ducts were wet; in another the duct containing cable 3 was kept dry, the others being wet.

Figure 5 shows the maximum temperatures versus duration of the overload for conductor and sheath of cable 3, both in wet and dry duct condition. The figure shows that the temperature difference between wet and dry ducts is about 10 C for a level of 75 C conductor temperature, increasing to about 15 C for a level of 90 C. Also, it can be seen that if a level of, say, 90 C is tolerated, then 125-ampere overload may be applied for nearly four hours with wet ducts, but only for about two hours with dry ducts.

Location of Cable in Duct Bank

It is known that cable temperatures depend on the location of the particular duct in the bank. The magnitude of this effect can be determined by the model. In connection with a load schedule as shown in Figure 4, maximum conductor temperatures versus location of the duct for various amperages were plotted on Figure 6. The diagram below the abscissa indicates the positions of the respective ducts. The temperature of cable 3 (dry duct) was not comparable with that of others and was not plotted. It may be seen that the center cable in the top row and the cables in the second row were the hottest. The corner cables, because of more favorable heat conduction into the ground, were the least hot. The maximum difference for a current of 265 amperes was 9 C.

Analysis of Temperature-Time Curves

Complete temperature versus time curves, as obtained from the model installation, permit immediate reading of maximum temperatures, as illustrated in the preceding sections. There are, however, two further kinds of information obtainable through an analysis of the curves, and these are dealt with in the following sections.

Relative Life of Cable Insulation

The following analysis is rather elementary and may be refined, if wanted, in several ways. The basic idea is that the cable insulation (paper and oil) slowly deteriorates chemically and when the amount of paper and oil that is chemically changed reaches a certain threshold, breakdown might take place, for instance, through thermal failure because of too high power factor. It is realized, of

Figure 8. Relative insulation life and maximum temperatures vs. duration of daily overload for cable 9

course, that under present loading conditions the life of the cable itself depends on many other factors, chiefly related to the sheath and partly of an accidental nature, and not so much on the chemical deterioration of the paper and oil. It is emphasized, therefore, that the following consideration does not refer to the life of the cable as a whole, merely to the probable life of the cable insulation. If, however, temperature limits are raised appreciably, the importance of chemical changes as a life-determining factor as compared with the other factors is increased.

The rate of chemical deterioration (oxidation, polymerization) may be generally expressed as me^{bT} with m and b constants and T = temperature. Such a law is assumed to hold in this case also. The total chemical change in one day is then given by:

$$m\int_0^{t_d} e^{bT}dt = mM \tag{8}$$

where t = time and t_d stands for one day. Since the function $T(t)$ is known from the model test, the integral M can be evaluated numerically. Let us specify equation 8 as written for a normal daily load. Let us now consider a particular higher load schedule and write the corresponding daily chemical change as

$$m\int^{t_d} e^{bT'}dt = mM' \tag{9}$$

the primed quantities referring to the specified over-load schedule; they too are known from the model test. If higher load is applied on a number of days, being a fraction f of the total number of days; if t_i' denotes the life of the insulation in days; if finally M_i stands for the total chemical change before breakdown takes place, then the following relation holds:

$$M_i = ft_i'mM' + (1-f)t_i'mM \tag{10}$$

the first term standing for the total change during high load days, the second for that during normal load days. From equation 10 the life is given as

$$t_i' = (M_i/m)/[fM' + (1-f)M] \tag{11}$$

The life could only be evaluated in absolute figures if the constant M_i/m were known, which is not the case. A relative figure for the life may, however, be calculated in the following manner. Let us write an equation corresponding to equation 11 for $f=0$, that is for a cable that does not carry high loads. If the life of such a normal cable is denoted by t_i, then we have

$$t_i = M_i/mM \tag{12}$$

Dividing equation 11 by 12, we obtain finally

$$t_i'/t_i = M/[fM' + (1-f)M] \tag{13}$$

in which only known data occur. Equation 13 gives the relative insulation life as a fraction of the life of a normal cable.

In the following evaluations $b = 0.0693$ was used because, with this value, an increase of the temperature by 10 C doubles the rate of the chemical deterioration. This is in keeping with many known chemical reactions,[8] although in other cases the rate is trebled for 10 C rise in temperature. Any other value, if preferred, may be substituted for the one assumed here.

In practice, overloads in the narrower sense of the word, are applied only a few days per year; in this case f is small, and equation 13 yields a relatively little decrease of insulation life. For the following calculation, however, we consider daily loads that are higher than the accepted standard. In this case f becomes unity and equation 13 takes the form

$$t_i'/t_i = M/M' \tag{14}$$

A load schedule, as mentioned previously with reference to the moisture condition of ducts, was analyzed according to equation 14. The data, obtained by means of the model setup, upon which the analysis was based is shown in Figure 7 specifically for cable 9. The computation was based on conductor temperatures. The integral M for the normal cable in each case was computed from an extension of the portion of the curve prior to the sudden rise due to the high load. This normal curve occurring with loads of 250 amperes is, of course, under equilibrium conditions the same every day; in the model test there is a slight increase of the general level because equilibrium has not been reached. The result of the analysis is shown in Figure 8. At the lower part are shown maximum temperatures obtained versus the duration of the high loads; at the top part is shown the relative life t_i'/t_i of the insulation, the life for normal load being unity. This additional information is of more practical value than the mere knowledge of peak temperatures because it also contains the time element during which the peaks prevailed. If, for instance, a probable reduction in life of about 20 per cent is tolerated, an overload of 125 amperes above 250 amperes may be applied for about two hours every day (under the condition of eight equally loaded cables in a bank).

Rate of Rise of Cable Temperature

A second kind of information that may be evaluated from the graphs obtained is the maximum rate of temperature rise. This rate might have significance in certain cases because it determines the rate of oil expansion which in its turn should not exceed certain limits. To be specific, let us consider a cable run, one section of which is located lower than the rest of the

Table IV. Computation of Duct Constant from Model Data

T_{dg}	L	H	C_D
29.0	0.77	7.7	0.61
33.5	0.39	17.3	0.62
35.0	0.41	17.3	0.62
40.0	0.43	17.3	0.67
42.0	0.46	17.3	0.66
44.0	0.48	17.3	0.66

cable. In the course of time, oil might gradually drain from the higher to the lower section, causing the latter to be fully impregnated. If the temperature rises and the oil has no time to flow from the fully impregnated low section into the neighboring ones, the lead sheath in the lower section expands; if the rise of temperature is too rapid, it might be damaged. It is obvious that more detailed information of this mechanism will be necessary before full benefit from a knowledge of the rate of temperature rise is derived.

As an illustration of such an analysis, a test was carried out in which a 3-hour overload of various magnitudes above 240 amperes was applied. The temperature versus time curve is not given for this case. The analysis of these graphs resulted in the curves in Figure 9. The lower part gives maximum temperatures and the upper part relative insulation life versus overload currents. The center part shows maximum rates of temperature rise per hour (figures valid for the field installation). As mentioned before, the maximum permissible limit of rate can only be calculated if the specific conditions for each case, such as the contour of the cable run and the plastic characteristics and tensile strength of the sheath, are known.

Scale Reduction in the General Case

In both the previous and present investigation only one cable or one duct bank was dealt with. As a result, the problem was treated as a 2-dimensional case, the third dimension, parallel to the cable, having no influence on the calculations. There are, however, practical problems for which this condition does not hold. Such a problem would be, for instance, the influence upon the cable temperature of a steam pipe running close to a cable duct at an angle with the latter. This problem is a three-dimensional one, and it is worth investigating briefly whether or not the scale reduction scheme can be used in this general case as well as in the special 2-dimensional case. This question is answered in the present section. No actual tests along these lines were carried out.

In order to answer this question, let us examine the equation[6] giving the temperatures at any point in space and any time if a spherical heat source generates instantaneously the amount of heat H_o. For our particular purpose, it is advantageous to replace H_o by Ht_o where H is the heat generated in unit time and t_o is a small time interval. The equation then reads:

$$T=\frac{Ht_o}{8\pi^{3/2}D^{1/2}\rho c r a t^{1/2}}\left[\exp\left(-\frac{(r-a)^2}{4Dt}\right)-\exp\left(-\frac{(r+a)^2}{4Dt}\right)\right] \quad (15)$$

where D = diffusivity, ρ = density, and c = specific heat of heat conducting medium, a = radius of spherical heat source, r = radius vector of any point in space, t = time.

What are the transformation equations if the form of equation 15 should remain unchanged? Material constants remain unchanged and the temperature T should remain the same. From the expressions in the bracket, it can be seen that we have, as in the 2-dimensional case.

$$r=qr_r \quad (16a)$$

$$a=qa_r \quad (16b)$$

$$t=q^2t_r \quad (16c)$$

Introducing these substitutions into equation 15 and dividing numerator and denominator by q^2, q is left over in the latter. Thus, H/q has to be identified with H_r, or:

$$H=qH_r \quad (16d)$$

If, therefore, a 3-dimensional installation is reduced by a linear reduction factor g, the total heat rate must be reduced in the same ratio.

This is the same result that was previously established for a cable, only in a more general form. A cable in a 3-dimensional sense has a definite length, and in the model this length is reduced by a factor q. Since the heat rate for the whole length is reduced in the same ratio, the heat rate per unit length of cable is the same, and in this form the result was formulated previously.

It follows that, by using equations 16a to 16d, any 3-dimensional heat conduction problem can be solved by means of a reduced scale model. If, for instance, a steam pipe crosses a duct run, both the diameter of the steam pipe and its distance from the duct is reduced in a ratio q. The length of the cable must be sufficiently long for the disturbance caused by the pipe not to extend to the ends of the cable. The temperature of the pipe is maintained at the same level in

Figure 9. Relative insulation life, maximum rate of temperature rise, and maximum temperature versus three hours daily overload for cable 13

the model as in the field. Transient heat flow from such pipes into the ground was treated in a separate paper[7] recently published.

In closing, it is pointed out that the present investigation, together with the previous one, completes to a certain degree the authors' work on this method. A possible continuation of the work depends partly on whether there is sufficient interest among cable users in applying the method to pertinent questions in this field. A possible application, one in which some interest has been expressed, is a determination of duct and soil resistances, sometimes referred to as duct-heating constants, for varying moisture content of the soil. Since the soil in the model can be irrigated artificially, these varying conditions could be maintained relatively easily in a reduced-scale model installation.

Discussion

R. J. Wiseman (The Okonite Company, Passaic, N. J.): I am glad to see that Gemant and Sticher have written another paper on the studies that they have made on reduced-scale model cable installations. In this paper they report on a comparison of field duct installations with the model set-up for ducts and show that fair agreement is obtainable in the model set-up. As field conditions are quite variable along a duct route, we cannot expect close agreement between laboratory tests and field tests, rather the laboratory tests can be considered as indicative of the magnitude of the temperatures to be expected. Also, our knowledge of the thermal constants for the various parts of the thermal circuits are none too good, so we cannot expect too close agreement of computed and test results.

I like very much the reporting of results with wet ducts showing how helpful it is to have water in a duct, as it seems to act as if the water short circuits the convection and radiation factors in the zone between the cable and the duct wall, thereby improving the conduction of heat to the duct tank.

As the authors state on page 3 of the paper, the model gives a means for determining duct heating constants, and I hope that it will be possible for a program to be set up to carry out a complete study of these constants. There are some of us who feel that a clearer understanding of the constants that we now use should be obtained, particularly when the thermal resistance of cables in ducts is compared to buried cables. The model setup that the authors use has a soil surrounding the duct bank having a thermal resistivity of 70 thermal ohms per centimeter.[8]

They report in Table IV of an average duct constant of 0.64 for eight cables in the duct bank as compared to the NELA value of 0.77. I believe we should take the constant for a 10-way duct bank, which is 0.74, instead of an 8-way duct bank, as the model set-up has the equivalent surface for radiation of a 10-way duct bank. Although the agreement between laboratory test and assumed constant is only fair, it does indicate that for the latter the earth thermal resistivity is low.

Figure 6 gives a good picture of how beneficial it is to have the cables in outside ducts only and that corner ducts are preferred locations.

I hope no one will get the impression from Figure 7 that daily overloads should be carried on cables with the reduction in cable life, as indicated in Figure 8. If load cycles as shown in Figure 7 exist, then the load factor should be found and the cable designed in accordance with this load factor, and allowable operating temperature. Overloads are supposed to occur only occasionally and usually for not over 300 hours per year.

I believe the authors have produced a method for the study of temperatures on cables in duct banks which can go a long way to obtaining some of the information that is needed both for transient and steady-state loading of cables. I hope that they will continue this work and in time make further reports to the industry.

Andrew Gemant and **Joseph Sticher:** It was gratifying to hear Wiseman's favorable comments on our paper. We also think that the suggested method might prove useful in solving some existing uncertainties concerning the loading of high-voltage cables. Whether we shall be able to continue this work depends on various circumstances, not all under our control.

Wiseman's remark concerning the frequency of overloads is correct. Daily high loads were used in the test only to illustrate the results of the proposed calculation of insulation life in a conspicuous manner.

Finally, it may be worth mentioning that the model method is applicable not only to buried cables, or cables in ducts, but also to extra-high-voltage cables in pipes. In case the pressure medium is oil, the application is quite straightforward. In case the medium is gas, the correction term for radiation, as explained in the paper with reference to ducts, must be applied, and the results thus obtained will then be close to expected field data.

An Electroacoustical System

ERIC A. WALKER
MEMBER AIEE

THIS PAPER describes the application of certain electrical and acoustical phenomena to the solution of a specific problem, namely, the finding of torpedoes which have been lost in the course of proof testing. The equipment explained consists of a mechanism for generating a supersonic signal which travels through the water or sediment in all directions. This signal is detected by a directive-listening hydrophone which can locate the approximate bearing of the source in both azimuth and depth. The latter equipment is portable and can be mounted on small locating vessels. By a proper search procedure, the torpedo can be fixed within a few yards probable error, from where it can be retrieved by a diver.

Although this application is a very specific one, the problem itself is much more general and has wider application. The principles of underwater signaling which are described have been developed largely within the past few years and have further applications in underwater detection, underwater signaling, geophysical prospecting, and in material testing.

The Specific Problem

Before torpedoes are accepted for use by the Armed Forces, each one must make a successful test run, in which it must run a course within specified limits of depth, direction, and duration. Such a test, therefore, demands that each torpedo must be risked in an actual run in the ocean or other suitable body of water. In these proof runs the warhead, which contains a detonator and explosive, is replaced by a water-filled dummy head. Usually a fully-armed torpedo ready for a war shot is not buoyant, and its total weight exceeds its displacement by some 300 or 400 pounds. To insure that the torpedo will float at the end of a trial run, advantage is taken of the lack of explosive, and the dummy warhead is filled with water or a salt solution of a predetermined specific gravity. This liquid is blown out of the warhead by air through a self-closing valve at the end of a predetermined run or when the engines stop. Displacing the water by air then renders the torpedo buoyant, and at the end of its test run, it should float on the surface, from where it can be sighted visually and retrieved. Unfortunately, the margin of safety afforded by this system is not large because of space limitations. Too frequently because of a failure of some part of the mechanism which results in incomplete head blowing, or because of other failures that prevent complete burning of the fuel, the torpedo does not become buoyant and therefore sinks to the bottom. It is unfortunate that those torpedoes which are erratic and get off course, sometimes ending miles from where they should be, show the greatest propensity to fail to come to the surface. It is also unfortunate that proof-testing stations are not located on clear water so that one can see the bottom and recover the torpedoes by simple visual search.

The specific problem, then, is to find some mechanism by which a torpedo can make its location known when it is on the bottom under several fathoms of water or even when it is stuck in the mud at the bottom of a test range. In more general terms, however, the problem is to locate any object which is operating in a medium where the usual signaling methods, such as visual or electromagnetic, fail.

Possible Systems of Detection

In this particular problem it is possible to provide the object which might later have to be located with some device which will indicate where it is. This is a sensible thing to do, since the percentage of those torpedoes which become lost is rather high, and there is no doubt that one will go to considerable expense to find it once it is lost. The system evolved is not applicable to finding those devices in which no such provision has been made. For instance, this system cannot be used to locate a sunken submarine or the wreck of an airplane which is on the bottom of the ocean unless sufficient foresight has been exercised to provide the projector part of the locating system in the lost object. This is now standard practice with submarines but obviously not with airplanes.

Various indicating systems were considered, among them those which might cause the emission or ejection of bubbles, heat, a dye, chemicals, or even a marker buoy. Such devices will be considered very briefly in order, enumerating their advantages and disadvantages and showing why all were discarded.

First, the ejection of a stream of bubbles. It is quite easy to provide a torpedo with a source of compressed air which can be released slowly, giving a train of bubbles which will be visible when they break on the surface of the water. In fact, a small compressed air supply at the 3,000 pounds per square inch pressure available in many torpedoes provides a bubble train which will last for many hours. The difficulties encountered in seeing bubbles, however, are quite obvious. Unless the bubbles are large, they cannot be seen for any great distance even with smooth seas, and if the sea happens to be disturbed or even mildly turbulent, they cannot be detected at all from a distance of more than a few feet. Another consideration is the drift of the surrounding water caused by river currents or by tides. Bubbles sufficiently large to be easily visible (about 1 inch diameter) rise with quite limited velocity, namely,

Paper 48-8, recommended by the AIEE communications committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted July 7, 1947; made available for printing November 25, 1947.

ERIC A. WALKER is head of the department of electrical engineering, Pennsylvania State College, State College, Pa.

Figure 1. A simplified line source

about two feet per second. Therefore, in a tide they do not come to the surface over the spot where they are released. For instance, bubbles released from a point 100 feet below the surface emerge 500 feet downstream in a 6-knot current. This large error greatly reduces the usefulness of such a system, especially when as in this case, the location must be accurate within a few feet. Perhaps the greatest disadvantage of the bubble system is caused by so many of the torpedoes sinking or driving themselves several feet into the mud on the bottom. This mud has sufficient weight and viscosity to prevent the ejection of the stream of bubbles, which of course renders such a system entirely useless.

The second method might be to generate heat in the body of the torpedo and detect the torpedo's presence by the rise in ambient temperature. At first glance this method seems quite promising, since temperature differences of the order of a fraction of a degree are quite easily recorded. The scheme, however, has all the disadvantages of a bubble system, resulting from the drift of the water or the loss of the body in mud, plus one other quite serious limitation. The ocean or even a small fraction of it cannot be considered as an isothermal medium, since the sun, the tides, and the flow of rivers and underground streams stratify the water with layers at different temperatures. Acute temperature gradients have been detected, and variations of 10 or more degrees within a few fathoms are not at all uncommon. In fact, the change in density at such layers makes it possible for submarines to sit stationary "on a thermocline".

A buoy scheme might be considered. A possible solution is to have the torpedo eject a light balsa wood buoy when it exceeds a certain depth or when its velocity falls below a certain predetermined minimum. The latter can be accomplished by a flap valve held in place by a trigger on which the water exerts a force while the torpedo is in motion. When the valve opens, the buoy is ejected, trailing a line attached to the sunken torpedo. The disadvantages to such a scheme are immediately apparent. First, a considerable length of line must be stowed within the body in such a way that it can unroll quite freely and with little restraining force. Again the effects of tides and currents are quite evident, since the buoy will trail far downstream unless its lift is considerable. The trailing or horizontal force is a direct function of the length of line, and tests show that the size of buoy which insures a rise to the surface in any appreciable current is excessive. The most serious objection to such a device, however, is that if the torpedo is immersed in mud, the release mechanism will not operate, and the buoy cannot rise to the surface.

Another solution which momentarily gave promise was the ejection of a dye similar to that used and so widely acclaimed for the saving of shipwrecked airmen when stranded in small boats. This dye, called fluorescein, gives a widespread and brilliant yellow mark if it is released on the surface of clear, nonturbid ocean water. Unfortunately, its effect is almost nil if the water is at all dirty, and because its specific gravity is about equal to that of water, it does not rise to the surface if released at any appreciable depth. Such a method proved to be quite unfruitful.

Other methods, such as changing the chemical content of the water, were suggested. Since it is possible to detect very small changes in oxygen content by methods which have been developed in physiological research, such a scheme was investigated. However, there appear to be random variations in the oxygen content of sea water, and such investigations were not pursued very diligently.

A much more fruitful method than merely putting out a marker device appears to be the generation of some phenomenon which can be propagated or transmitted through the mud and water. In considering such methods, one immediately thinks of light waves, infrared radiation, electromagnetic waves, and sound waves.

If a light source is placed in the lost body, one can expect the intensity to decrease as the inverse square law, at least as a first approximation, if one neglects such factors as reflection and absorption. Unfortunately, in practice absorption cannot be neglected. Measurements show that the absorption of the total visible spectrum is approximately 6 decibels every 10 meters even in the clearest sea water. In other words, one half of the energy of a plain wave is lost every 10

meters.[1] This loss is increased by turbidity, bubbles, foam or jetsam. Of course, it would not be necessary to use light in the visible spectrum, since detectors other than the eye can be used. Although the entire light spectrum has not yet been explored, there is little reason to believe that there are preferred frequencies which are not absorbed at this rate, although there is some slight evidence to show that some frequencies in the green-yellow spectrum are absorbed less than others. In summary, to the extent of present knowledge, the absorption of light waves, including the infrared band, is too great to make their use practical.

Electromagnetic waves in the radio-frequency spectrum might be used, and indeed submarines have been known to receive radio signals when their antennas are submerged. Here again the absorption of such waves is tremendous, increasing very rapidly with increase in frequency. The loss is about 3.4 decibels per meter at 10 kc and about 34 decibels per meter at 1 megacycle. Although one avoids attenuation by using the longer wave lengths, a consideration of the problem shows that the transmitting and receiving equipment become excessively large at these frequencies. Moreover, the size of antennas necessary to permit direction finding increases very rapidly as the frequency is lowered. Another phenomenon which has not been sufficiently explored is the attenuation of electromagnetic waves when they pass from sea water into air or vice versa. We only know that the loss for these conditions is very high. Little work was done with this medium.

The use of sound waves offers more promise than any of the former schemes. Sound travels in sea water with a speed of approximately 5,000 feet per second,[3] so that no particular difficulty is caused by the delay between the transmission and reception of sound signal. However, sound energy, like that of light, is subject to absorption when passing through sea water, but fortunately in this case the amount is not prohibitive. Some measurements show that the absorption of 28 kc sound is about 0.003 decibel per meter, while at 90 kc it is about 10 times this amount. In other words, the energy of 28-kc sound drops to about one half in traveling through 1,000 yards.[2] Again although there is something to be gained in going to the longer wave lengths, it is found that the transmitting apparatus becomes more unwieldy at the lower frequencies, and the receivers must be large in order to get proper directivity. There are several other advantages which favor the use of underwater sound. First, sound waves not only travel through water but will penetrate mud. Second, it is possible to build efficient supersonic speakers and receivers of reasonable size. Third, the method does not require very large amounts of acoustic power.

There are a number of disadvantages, but none of them is important enough to make the method unusable. The most prominent among the disadvantages is the refraction of the sound caused by temperature gradients in the water or changes in salinity.[4] This limits the range and makes the apparent direction in depth somewhat erroneous. Another is the background noise which is present in the water and which has many causes—waves, rain on the water surface, the noise caused by the machinery of boats and the cavitation of their propellers, and lastly the noises caused by shrimp, some kinds of fish, and other marine life.

The Design of an Underwater Sound System

The choice of the frequency for which the system should be designed is influenced by several factors. As pointed out previously, the attenuation of sound waves approximately doubles each time the frequency is doubled. However, one must have an appreciable directivity to the listening hydrophone in order to tell the direction from which the sound is coming.* For a given directivity, one approximately doubles the size of the hydrophone as the frequency of the system is halved. Therefore, the choice of a working frequency partially becomes a compromise between these two factors. This point can be illustrated in another manner. Consider Figures 1, 2, and 3. Figure 1 shows a sketch of a "line source" type of transducer—a simple metallic tube which can be induced to vibrate radially. When this device is used as a projector and is immersed in water, a

*The terms "transducer," "hydrophone," and "projector" are sometimes used quite loosely. The following definitions will be used here: The transducer is any device which transforms one kind of energy into another, that is, electrical to acoustic energy or vice versa. A hydrophone is a device whose principal use is to convert sound waves in water into an electric signal. A projector is a device whose principal use is to convert electric energy into acoustic energy in the water.

Figure 7. The finished oscillator ready for installation

polar graph of the sound intensity can be plotted around any axis at any chosen frequency. Since a transducer is a bilateral-energy converter, the same graph governs its performance as a projector or as a hydrophone. Figure 2 shows the patterns at 40 kc for a line source 10 inches long having a diameter of about 1 inch. In this diagram curve A is a plot of the theoretical sound intensity around the X axis. Note that this curve is shown on a logarithmic or decibel scale with the intensity in the strongest direction taken as the base or reference intensity. The most prominent feature of this curve is its pronounced lobe in the zero direction and the three secondary lobes to each side of the major lobe. Such a curve is quite familiar to the acoustic or radio engineers, since it is the familiar radiation pattern of a straight line source or an antenna.[5, 6] Curve B is a curve of the recorded-sound pattern for this transducer. The major lobe has been moved 10 decibels for convenience in plotting. The discrepancies between curves A and B are partly a result of the construction of the transducer and partly a result of errors in determining the curve. Any practical transducer must have an electric winding and a protective covering which tend to produce discontinuities which show as overemphasized lobes or shadows. There is always difficulty in recording the pattern of a transducer, since one cannot find a homogeneous medium in which to make the measurement. Reflections from the edge of the water and from the surface and bottom are always present to give partially erroneous readings. Curve B is also shown on a decibel scale. It is seen that the sound emitted along a 36 degree radial line is 20 decibels less than that along the reference axis. Conversely, the response to a plain-pressure wave oriented at 36 degrees gives 20 decibels less voltage or one per cent of the power given by a like wave at 0 degree. It might also be noted that the major lobe on the 0 axis is 20 degrees wide at the half voltage points, that is, the points 6 decibels down from the maximum.

The curve marked C in Figure 2 is a graph of the sound pressure around the Y axis. For this orientation the projector acts like a point source, and the field has a circular symmetry.

Figure 3 shows clearly the effect of a higher frequency or shorter wave length. At 100 kc the major lobe should be much more narrow than at 40 kc, and there should be nine secondary lobes in each quadrant. Because these lobes are so narrow, the theoretical pattern has not been plotted. However, it can be seen that at 100 kc the major lobe in the pattern around the X axis is only 8 degrees wide at the 6-decibel points, and many of the minor lobes have almost disappeared. On the other hand, the pattern around the Y axis is almost unchanged.

It is fairly obvious that any electromechanical system which is expected to work in resonance, as this is, will show a familiar resonance type curve as one plots some property, such as the magnitude of the vibration, as a function of frequency. In order to produce highest efficiency, it is desirable to operate more nearly at resonance. Figure 4 shows a resonance curve for the transducer.

Fortunately, one is not limited to the frequency range easily heard by the ear, since one can employ beat frequency techniques and shift the chosen transmitting frequency to an audible one. Actually, a frequency of approximately 25 kc per second was chosen. This sound, which is in the supersonic range, was converted to an 800-cycle note for listening at the receiving end. In passing, it might be noted that at 25 kc the wave length is approximately $2^1/_2$ inches in water.

The Acoustic Radiator

The next design consideration is to choose an efficient acoustic radiator. Obviously, a knocker or doorbell might be used, but the amount of sound emitted by such a device in the usable region is small, and the efficiency is very low. Within the past few years, considerable work has been done in the theory and design of both magnetostriction and crystal transducers. In this case either type might have been used, but a magnetostriction one was chosen because of its simplicity and ruggedness. In essence, the projector consists of a nickel tube mounted on a small metallic diaphragm. The nickel tube is given a magnetic bias by inserting an "alnico" magnet through its center. Vibration is produced by an alternating-magnetic field induced by a current in a coil which surrounds the tube. This arrangement is such that vibration takes place in the longitudinal direction rather than radially. By choosing a length of tube which is mechanically resonant at the proper frequency, high efficiency of electric-to-acoustic power conversion can be obtained. The purpose of the diaphragm is to match the mechanical impedance of the tube to that of the surrounding water in which one wishes to produce the supersonic-sound field.

Figure 5 shows a cut-away view of a magnetostriction projector. A is a metal cap. B is a thin-cylindrical "alnico"

Figure 8. A self-contained unit consisting of battery, oscillator, and projector. This type is for airplane launching

Figure 9. An exploded view of the receiver hydrophone

Figure 12. The completed receiver

magnet used to provide the proper magnetic bias in the nickel tube. *C* is an eddy current shield which surrounds the magnet. *D* is the winding, and *E* shows the nickel tube itself. Note that the nickel tube is slotted to reduce eddy currents. It is mounted on a small brass boss *F* which is connected to a rubber diaphragm *G*. This projector, in a favorable mounting, will produce a reasonably spherical acoustic field and at a distance of one meter will produce a field strength of about 30 decibels above one dyne per square centimeter. This represents an approximate energy conversion of about 10 per cent. Actually, the sound so produced is well above background noise at a distance of 1,000 yards.

A simple and very rugged electrical oscillator is necessary to provide the driving power for the electro-acoustic transducer. Many of the torpedoes to be tested contained a battery which was used for main engine propulsion. Since it was possible to design a circuit to work off the main battery voltage, this provided an almost unlimited source of power for the transmitter. The particular system chosen used two 3Q5-GT tubes and consisted of a frequency-stabilized oscillator driving a single power stage. The circuit is shown in Figure 6, while Figure 7 shows the assembled oscillator ready to mount.

Some versions of the device were constructed for use in torpedoes which operated with turbines and therefore had no storage battery. In these cases the whole assembly, consisting of projector, oscillator, and battery power, was assembled in a water-tight can which could be removed in one piece. One type of this assembly is shown in Figure 8. This particular version is also designed to be dropped from aircraft at rather high speeds.

The Acoustic Receiver and Circuits

The acoustic receiver is not quite as simple as the transmitter. In the first place, because it is designed to pick up small amounts of energy, it must have high sensitivity. Moreover, in order to permit some degree of direction finding, a certain amount of directivity is required in the listening hydrophone. The particular version finally adopted consists of one or more tubes of nickel surrounded by an electrical winding in which the signal is generated. Because it is necessary to attach this receiver to a small retriever vessel and to listen while the boat is underway, the assembly is mounted in a streamlined housing. This posed another problem, namely, the finding of a material which could be machined easily and which offered approximately the same acoustic impedance as sea water. Fortunately, lucite meets both requirements.

After some experience with this system, it was found desirable to provide some degree of search in depth. In the construction of the hydrophone, it was found necessary to place an acoustic baffle approximately one-half wave length behind the vibrating element in order to increase the front-to-back discrimination, or the ability to hear sounds ahead of the hydrophone better than those behind. The idea of making this baffle in such a manner that it could be rotated in order to throw the listening beam up or down was tested and found to work. This, then, provided an easy method of tracking the source of sound as the receiving vessel passed overhead.

Figure 9 shows an exploded view of the finished receiving hydrophone. *A* is the actual acoustic vibrator, and *B* is the rotatable baffle. The shell is formed completely from lucite.

Figure 10 shows the patterns of this hydrophone in both vertical and horizontal planes. It is seen that in neither plane is the major lobe very sharp. This again is a compromise, since although a sharp lobe assists in obtaining bearing accuracy and improves the signal-to-noise ratio, one might pass over a noise source if searching rapidly with an extremely sharp-lobed transducer. The sensitivity of this particular receiver is approximately 100 microvolts per bar in a 1,000-cycle band centered at 25 kc.

Figure 11. The receiver circuit

The complete receiving circuit is shown in Figure 11. This is a rather conventional circuit in that it consists of two stages of tuned radio frequency amplification and a beat frequency oscillator, reducing the 25 kc note to 800 cycles, at which point there is further amplification before the output stage. The output indication consists of a speaker or headphones in parallel with a meter for visual indication. A complete assembly ready for shipboard installation is shown in Figure 12.

Search Procedure and Use

At a later date a number of refinements were added, such as making the receiving head trainable from the wheelhouse of the receiving vessel. However, in most cases the coxswain found it only necessary to don earphones and to steer the vessel in the direction of the loudest sound. The method of search is rather simple. The boat is merely steered in the direction of the loudest sound, and an attempt is made to train on the beam in a vertical as well as horizontal plane. When the ship passes over the source of sound, there is a rather noticeable and abrupt drop in sound intensity. At this point a buoy is launched, and another search is made from a different tack. If the two or three locating buoys are relatively close together a diver can be sent down to locate and retrieve the lost torpedo. In some installations it was found desirable to equip the diver with a portable receiving hydrophone which he could carry on his chest. In most cases the signal from this hydrophone was monitored on the deck of the retrieving vessel, and the diver was given verbal instructions concerning which direction he should face and how far he should go.

That the device and system were successful is easily shown by facts. The Navy has written that this system at one installation accounted for the recovery of over 250 electric torpedoes and over 175 steam torpedoes. The same system with diver's hydrophone accounted for 60 additional electric torpedoes and about 100 steam torpedoes, these recoveries representing a saving of over $14,000,000. However, these figures should not lead one to suppose that this is the only use of such a system. This is but one very specific application which the need made it necessary to develop. Many other uses for sound waves are being found in the realm of testing metals for flaws, underwater signaling, the plotting of geophysical profiles, and even in the design of time delay lines for radar trainers.

Obviously such a development as that described in this paper is the result of the work of a number of men. This system was developed by a team of scientists working at the Harvard Underwater Sound Laboratory during the war years. Among those who made major contributions are Dr. Harvey Brooks, Dr. K. C. Morrical, R. R. Thompson, L. N. Miller, and others.

Discussion

T. A. Daly (Westinghouse Electric Corporation, Sharon, Pa.): I should like to compliment the author on his very comprehensive discussion of the problem of locating lost torpedoes. The possible systems outlined are very reminiscent of the early days of electric torpedo development at the Westinghouse Ordnance Division, as several of these methods were used at our Lake Pymatuning range before supersonic locators became available. One method not mentioned is the Navy device known as a torchpot, consisting of a canister containing calcium phosphide which, upon contact with water, gives off a stream of gas bubbles. These bubbles ignite upon reaching the surface, resulting in a momentary flare and a puff of white smoke.

The acoustic locator which we used most was a self-powered unit developed by the Naval Ordnance Laboratory and produced a 45-kc signal of very good directivity. It had, I believe, an additional advantage in that the signal was pulsed, making it considerably easier to distinguish it from other noises in the area. Our search procedure with this unit was slightly different, in that the diver's headphones were also connected to the receiver and he was able to guide himself to the torpedo, instead of following instructions from above. During more than four years of experimental firing of nine different types of torpedoes at Lake Pymatuning, not a single unit was permanently lost.

I might mention that considerable testing is done in depths of water at which divers cannot operate, and under these conditions, of course, locators of any type are of no value. For this reason, the tendency has been to run the torpedoes whenever possible in a buoyant condition and to eliminate head-blowing equipment. However, mechanical proving runs will continue to be made in shallow waters, and here such locators are of definite value.

R. B. Vaile, Jr. (Armour Research Foundation, Illinois Institute of Technology, Chicago, Ill.): Before commenting specifically on the very interesting paper which was so ably presented by Walker, may I first express my wholehearted agreement with his question regarding the logic of the Navy's decision to proof test every torpedo. It is my recollection that approximately the same proportion of torpedoes fail on rerunning of the proof test as on the first run of the proof test.

The importance of retrieving torpedoes from the bottom became obvious early in the war to most of the organizations involved in torpedo development, among which are included the Naval Ordnance Laboratory the Bell Telephone Laboratories, and the Westinghouse Corporation, in addition to the group at Harvard with which Walker was associated. All these groups were first impelled to develop methods for retrieving torpedoes primarily in order to save the man-hours of development time which had been expended on each of the experimental torpedoes.

It was also apparent to these groups, after they had been in contact with the situation for a short time, that there was a problem of at least equal importance in the recovery of production torpedoes in order to save the production man-hours which had entered into their construction. For these reasons, each of the organizations mentioned ultimately developed and used one or more special devices for aid in the recovery of submarine torpedoes. Sonic generators covering much of the range between 10 and 50 kc were used. While the Harvard group used magnetostriction transducers, I believe all the others used piezoelectric transducers.

The sonic equipment developed by the Naval Ordnance Laboratory made use of a frequency of approximately 45 kc and was distinguished from all the others in being of the pulsing rather than the continuous type. The pulsing technique had the advantages which are, of course, well known in their equivalent application in radar as follows: First, a much larger power per pulse could be obtained from an energy source of limited extent. This enabled the Naval Ordnance Laboratory device to be self-contained and, hence, to avoid the necessity for electric connections from the outside to the inside of the torpedo. Second, there is a rather considerable improvement in the signal-to-noise ratio, both because of the increased power during a pulse and also because the problem of standing waves and reflections from the surface does not confuse the listener. In addition, the pulse repetition rate was made adjustable in these devices so that, if several torpedoes were on the bottom simultaneously, they could be distinguished from each other by the different pulse rates.

As soon as such aids to the location of torpedoes, as have been described by Walker and the others mentioned here, were in widespread use, another bottleneck in the recovery of torpedoes appeared. This was the difficulty of obtaining sufficient divers to complete the recovery after the location of the torpedo had been determined. For this reason the buoy method mentioned by Walker was developed to a considerable extent by the Naval Ordnance Laboratory. This development took the form of a buoy which was impelled to leave the torpedo by a small powder charge which was sufficient to expel the buoy through several feet of mud. As a further part of this equipment, when the buoy was picked up by the retriever launch, a small steel cable was lowered using the buoy line as a messenger and was engaged by an automatic latch attached to the torpedo. The torpedo was then raised to the surface by this small steel cable and towed to the dock where it taken out of the water.

Eric A. Walker: The discussions by Daly and Vaile both bring out the fact that equipments similar in nature were constructed by the Westinghouse Company and by the Naval Ordnance Laboratory. As a matter of fact, the development of the equipment described and the one at the Naval Ordnance Laboratory proceeded in parallel lines of attack and with some exchange of information. The fact that one group arrived at the conclusion that "pinging" was best, and the other that a steady-state signal was best, is a natural consequence of separate developments. There are arguments in favor of each system. As pointed out in one of the discussions, a pinging system allows one to differentiate more easily against background noise. It also allows one to put more energy into the water if the limitation in energy arises from either the heating of the elements or lack of an adequate battery supply. This is not strictly true if the limitation is caused by the cavitation of the water on the face of the transmitting hydrophone. However, it has been shown that for very short pulse lengths, one can attain greater pressures without cavitation than with longer pulses. In neither of the equipments described was cavitation a limitation.

There is one advantage in favor of the steady signal which cannot be overlooked and that occurs when the receiver has a relatively narrow beam pattern. If one wishes to scan rather rapidly throughout the entire 360 degrees in azimuth, one can be more sure the sound source will be heard if the sound source is a steady one. If it is a pinging device, one may sweep so rapidly that the lobe of the receiving hydrophone passes by the transmitter while it is not transmitting and so miss the signal. These are minor points and do not affect the usefulness of either system in any serious manner.

It is pointed out by Daly that this type of locating device is useless if the water is so deep that the divers cannot retrieve. This is absolutely true and many attempts have been made and are still being made to devise retrievers which are automatic in operation and which will do something to return the torpedo to the surface. Undoubtedly, one or more of these plans will be advanced to a successful conclusion.

The argument between piezoelectric and crystal transducers is an old one. Actually, there is not much to choose between them. If a transducer can be made for this type of use, using the piezoelectric principle, then it can be made using the magnetostrictive principle. This would not be true if extremely high frequencies were used. There is little argument as to which system and which type of transducer is the most rugged since both of them are quite adequate for this purpose. As a matter of fact, there is little difference in cost, and in cases like this cost is not of any great consequence since the equipment to be protected is many times more valuable than the protecting device itself.

FCC Diathermy Design for Low Harmonic Radiation and Good Frequency Stability

E. W. CHAPIN
NONMEMBER AIEE

W. K. ROBERTS
NONMEMBER AIEE

M. C. MOBLEY
NONMEMBER AIEE

FOR SOME YEARS the number of diathermy machines employed for therapeutic heating has been increasing, and at the same time the radio frequencies employed by these machines have gradually become of greater and greater importance in the communications industry. During and after the recent war the use of high frequency energy for industrial heating processes reached unprecedented proportions. These factors, operating in the same direction, have given acceleration to the development of critical interference problems. Besides the problems arising from the fundamental frequencies employed by diathermy and industrial heating equipments, the radiation of harmonic emissions has become of great importance because of the use of the frequencies from 54 megacycles and up for emergency, frequency modulation broadcast, and television services, in which diathermy and industrial apparatus and broadcast and other receiving apparatus will be operated in close proximity, as well as the danger of interference to radio aids to navigation.

Extended consideration was given the problem, and after hearings had been conducted, Part 18 of the Rules and Regulations Relating to Industrial, Scientific and Medical Service was finally adopted by the Federal Communications Commission in June 1947. These rules were intended to prevent interference in the majority of situations, with full realization that in a number of cases interference still will be experienced. Additional corrective measures will be required in these particular cases. The technical rules finally adopted represented a compromise between the requirements of the communications services and users of high frequency heating devices. The problem of interference originating from the operation of industrial heating and diathermy equipment received international consideration at the International Radio Conference held recently in Atlantic City and resulted in an international allocation of frequencies for the operation of such devices.

At the hearings preceding the adoption of the rules by the Commission, certain

Paper 48-10, recommended by the AIEE communication, electric heating, and applications of electricity to therapeutics committees, and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted November 12, 1947; made available for printing December 26, 1947.

E. W. Chapin, W. K. Roberts and M. C. Mobley are chief, assistant chief, and engineer, respectively, of the laboratory division, Federal Communications Commission, Laurel, Md.

The project was carried on under the direction of G. E. Sterling, chief engineer, Federal Communications Commission. Valuable assistance was received from George Ikelman, John E. Knight and the entire laboratory division staff.

Figure 1. Circuit diagram of the diathermy unit

Figure 2. The oscillator unit

The oscillator tubes are in the front half of the upper compartment, and the plate tank circuit is in the rear half. The plate tank fine-tuning adjustment knob and the radio-frequency output connector are at the top

manufacturers raised a question as to the practicability of economically satisfying the proposed requirements. When this question arose the Commission's laboratory at Laurel, Md., was instructed by the chief engineer to undertake a project to develop a self-excited diathermy machine of adequate therapeutic value, meeting the requirements of the Commission's rules covering such apparatus, for the 27.320 megacycle band. The idea was simply to show that the proposed rules could reasonably be satisfied if certain precautions were taken in design and construction and not to develop the best possible equipment or to develop a prototype which would be followed by the industry. The following remarks mention diathermy specifically, but the principles outlined are also valid for other types of high frequency devices.

Many diathermy machines which have been submitted to the Federal Communications Commission Laboratory for tests in regard to compliance with FCC rules have failed to pass such tests. The most frequent shortcomings are

1. Inadequate frequency stability under load variations.

2. Excessive radiation of harmonics of the fundamental frequency.

Deficient frequency stability in most cases was due to use of an unstabilized power oscillator directly coupled to the load. This type of circuit for generating radio frequency power dates back at least to 1916, and has generally been abandoned as obsolete for ordinary communication purposes for a number of years.

Harmonic radiation from these machines is of two types. (1.) That due to radiation from the generator as the result of insufficient shielding; and, (2.) that due to radiation from the load circuit and applicators. The former may obviously be mitigated by shielding and the latter may be reduced to the necessary extent by the design of the coupling circuit to discriminate against the harmonics.

It should be emphasized that the design of the subject diathermy unit was completed and the final model was produced several months before any commercial models were submitted which met the new requirements. Hence, it should not be construed that the design is based on information gleaned from examination of them. Furthermore, as will be made evident in succeeding paragraphs, there is nothing new or radically different in this design that was not known and practiced by many engineers in other fields of the electronic and communication art for a number of years. The Laboratory staff merely applied these standard engineering methods to the particular case of diathermy apparatus design.

Design Principles

Frequency Stabilization

There are several alternatives which provide frequency stability independent of load variations, such as crystal control and a master oscillator power amplifier. In the present case, where economy of tubes and component parts is desired, an electron-coupled power oscillator was used. See Figure 1 for the circuit diagram. In a pentode oscillator of this type the control grid circuit is isolated from the plate circuit by the electrostatic shielding effect of the screen and suppressor, each of which is at radio-frequency ground potential. In our case the grid and plate circuits are each tuned to 27.32 megacycles. The grid circuit could be tuned to 13.66 megacycles, further reducing the effect of load variation on frequency, at some sacrifice in output power. It will be noted that at radio frequency the plates of the two oscillator tubes are operated in parallel, while the grids are connected in push–pull. Hence, even if there is plate-to-control-grid feedback, such feedback in the active tube is practically neutralized by the corresponding feedback in the inactive tube. In the oscillator described the maximum frequency variation over the entire range of applied load encountered in diathermy service was 12 kilocycles at 27.32 megacycles. This compares with some self-excited diathermy units which showed a frequency variation of as high as 2,000 or 3,000 kilocycles at 27.32 megacycles.

Figure 3. Schematic diagram of the output tank circuit

Figure 4. The output tank circuit

Figure 6. The plate tank circuit, opened for inspection

The capacitance is that obtained between the inner and outer boxes. The tuning adjustment is by means of a metal vane moved by the knob

The frequency drift due to warm-up and voltage variations could be compensated but for the sake of economy and simplicity no such measures were taken. The width of the assigned band easily accommodates the 56-kilocycle drift measured over a full load run of six hours. The frequency variation with voltage results in combined amplitude and frequency modulation, but the sideband energy is confined to the assigned band.

Power Supply

Reference to Figure 1 shows that the oscillator is connected in the conventional two-tube self-rectified circuit in which only one tube is operating on each half cycle of the applied voltage. This arrangement is simple and economical, doing away with rectifiers filters, and the necessity for a time delay between the application of filament power and load. The disadvantages are the reduced output per tube and increased peak voltage for a given power output. The design could be altered to include rectifiers feeding the oscillator unfiltered direct current, thereby reducing these disadvantages. The rough note is tolerable of itself so long as the frequency stability is adequate to keep the operation in the assigned band and the harmonic intensity is in compliance with the regulations.

Shielding of the Oscillator

Refer to Figure 2. Here we see the oscillator unit completely enclosed in a metallic enclosure which is entirely independent of the outside metal cabinet. In this way there is the equivalent of double shielding. No radio-frequency tank currents flow in the outer cabinet. The oscillator is a complete power-generating unit, fed from the 115-volt 60-cycle power line, delivering its radio-frequency output to a coaxial cable connector. The control cable is fed through a shield braid. It was desirable to shield the tubes with a perforated metal cover.

Output Tank Circuit

In diathermy work it is essential that the power be delivered to a wide range of loads with several types of applicators. Generally speaking, the applicators fall into two broad classes:

1. Inductive, including cable, drum, disk, and hinged drum. This category generally comprises a conductor about 10-feet long, coiled into the configurations mentioned. The over-all length is such that the applicator is resonant at roughly the operating frequency.

2. Capacitive, including pads, cuffs, and air-space. These applicators are in a class which is used to treat the patient with electric fields. The length of the leads modifies the impedance presented by the capacitive plates to the output circuit.

All of these applicators are normally used with wide variations of spacing and configuration, in order to apply the energy to the desired part of the body in the intended manner, and with these variations there goes the large range of resistance and reactance into which the diathermy must feed power.

A number of load circuit variations have been used in the diathermy art. The one shown in Figure 3 and Figure 4 was adopted for the present design because the shunt capacity to ground offers a further reduction in harmonic radiation. All applicators commonly employed in diathermy treatments may be used with the circuit, all connecting to the same pair of terminals.

Coupling Circuit

The load circuit is link-coupled to the oscillator for three reasons:

1. The load circuit may be physically separated from the oscillator, as in our design.

2. The oscillator and load tank circuits may be well shielded from each other to make the desired mode of coupling the only important one.

3. Such an arrangement can employ two link coils, one at each tank, each of which can be shielded against capacitive coupling, thereby doubling the effectiveness of the electric shield.

Figure 5. Details of the electrically-shielded link coupling coils used between the oscillator and output tank circuits

Figure 5 is illustrative of the type of shielded-link coupling coil which is used. This link will be recognized as the same as the shielded-loop antenna used for low-frequency direction finders and field-intensity meters. Other forms of shielding, such as the Faraday screen, are effective provided the impedance to ground from all points on the shield is low at the highest frequency harmonic which is to be considered. Considerable harmonic energy exists up to at least 400 megacycles in an ordinary 27.32-megacycle diathermy.

Oscillator Tank Circuit

Efficient operation of class *C* oscillators and amplifiers requires the plate current to consist of short-duration pulses which occur at the minima of the plate voltage wave. The plate-current pulses are very rich in harmonics, becoming more so with the shorter pulses that accompany high efficiency operation. The object of our tank circuit design is to allow reasonably efficient operation and at the same time provide freedom from radiated harmonic energy, either from coupling into the load circuit or from direct radiation from the tank circuit.

Figure 6 shows the tank circuit construction. The capacitance is obtained between the inner box and the outer shield. In this way the plates of the tubes are connected to ground by a high capacitance, actually about 80 micromicrofarads, and the capacitor itself has no leads. The result is that the harmonic components of the plate-current pulses flow to ground through the capacitor, never reaching the inductance, which has a much higher impedance. If the capacitor had leads of appreciable length there would be, in effect, an inductance in series with the circuit from plate-to-ground and the higher harmonic frequency components of the plate-current pulses would divide, some passing to ground through the circuit described, and some through the tank coil. If a significant fraction does pass through the tank coil, energy will be transferred by the link circuit to the applicators in spite of the shielded link coil, since the shielding is not effective against inductive coupling. The applicators serve as an antenna and excessive harmonic radiation is produced.

Therefore, the basic requirements for low harmonic radiation are

1. A low impedance path from plate-to-ground, achieved through the use of a high capacity, which has the important characteristic of negligible lead length and consequently low-lead impedance.

2. Confinement of the output coupling means, so that coupling is inductive only, and that such inductive coupling is made only to the tank coil.

With respect to part 1 it might have been possible to employ a conventional variable air capacitor or a vacuum capacitor. However, to obtain the benefits desired it will be necessary to employ them in such a way that the lead inductance is very small, as outlined before.

Figure 9. The diathermy, ready for operation, with air-space treatment arms connected

Cable and pad electrodes on the floor

Figure 8. The complete diathermy installation in its cabinet, showing the relation between the components

Figure 7. A proposed power-line filter for the prevention of harmonic coupling to the power line

Power Line Filter

Design of a low-radiation diathermy unit requires that the power line leading to the unit be well isolated from harmonic fields. If it is not, it will be found that the diathermy machine and power line will operate as a large antenna system and spoil the remainder of the design.

In the unit described the radio frequency tank circuit is completely enclosed in a compartment separated from the power cord entrance, so simple mica by-pass capacitors were found adequate. To be effective it is necessary that the capacitor show a low capacitive reactance at frequencies as high as 400 megacycles. A slight amount of inductance in series, such as from an inch or two of leads, will almost void their effectiveness at the highest harmonic frequencies.

Button-mica or lead-through-type capacitor would be ideal for this service because their leads are negligible in length. Sufficient capacity must be used to by-pass the low frequencies. Figure 7 shows a proposed power line filter design for diathermy which should be highly effective. Here each line wire is led to a pi-filter section. It is important to shield the entire filter because if it were mounted in the open in a diathermy cabinet there would be coupling from the intense harmonic fields within the oscillator to the series choke coils.

Performance

The characteristics of the complete diathermy described are as follows:

1. Frequency variation with all possible manipulation of external loads and controls ±12 kilocycles.

2. Frequency variation when operated continuously into a fixed full-load—56 kilocycles. (Frequency variation allowed by type approval section of FCC Rules—±112 kilocycles from 27.320 kilocycles.)

3. Harmonic field intensity—maximum of 5 microvolts per meter at 1,000 feet. (Harmonic field intensity allowed by type approval section of FCC Rules—25 microvolts per meter at 1,000 feet.)

4. Therapeutic effectiveness—tested by Council on Physical Medicine, American Medical Association, through co-operation of Howard A. Carter, Secretary of the Council, and found to satisfy its requirements.

5. Power output—approximately 150 watts. The output fluctuates above and below this value, depending on the particular load arrangement.

Summary

This paper has set forth the principles which pertain to the elimination of frequency instability and harmonic radiation from diathermy equipment, illustrating the application of the principles with an actual model. In this way it is hoped that emphasis will have been placed on the manner of obtaining the results as well as on the principles. The problem of high frequency harmonics requires facility with high frequency techniques.

Discussion

E. L. White (Federal Communications Commission, Washington, D. C.): This paper affords a convenient opportunity to point out the seriousness of the consequences of unnecessary radiations.

At 3:15 p.m., Eastern Standard Time, on November 26, 1947, the supervisor of Station WSY, one of the stations serving international aircraft flying the North Atlantic, reported serious interference on all of the 6 megacycle frequencies used for air-ground communications. This same interference was observed and reported by a similar station, VRT in Bermuda. This report was referred to the Federal Communications Commission for investigation, and the source was found on December 1 by means of a radio-direction finder network to be in the vicinity of Johnstown, Pa. A mobile direction-finding unit was dispatched from the Philadelphia Office of the Federal Communications Commission to Johnstown and on December 3 located the interference to be originating in an industrial heater located in a chair manufacturing plant. The management of the chair factory immediately notified the manufacturer of the industrial heater, who in turn dispatched a representative to take necessary corrective action. Additional tests made on December 19 indicated that the interference had been eliminated.

A multitude of services occupy the radio frequency spectrum and actively use frequencies as high as 10,000 megacycles. Equipment is being designed and placed in service which will occupy frequencies up to 30,000 megacycles. Many of these services are intimately connected with safety. One of many good examples is "GCA" (ground controlled approach), a device using radar principles and procedures to guide aircraft to runways under conditions where the pilot cannot see the ground or his surroundings. It is easy to see the danger to life and property should interference destroy the utility of such a system at a crucial moment.

The Federal Communications Commission's rules provide certain frequencies which may be used for industrial, scientific and medical purposes without the necessity for shielding. These provisions were adopted in realization that for certain applications shielding was impractical. If other frequencies are to be used, public safety demands that the manufacturer of the equipment, as well as the user, take any necessary steps to insure that any radiation which may inadvertently result during the use of the equipment is contained within the premises on which the equipment is located.

D-C Amplifier Stabilized for Zero and Gain

A. J. WILLIAMS, JR.
MEMBER AIEE

R. E. TARPLEY
MEMBER AIEE

W. R. CLARK
MEMBER AIEE

Synopsis: An electronic amplifier for d-c measurements is described in which the zero is stabilized by the use of a contact type of modulator vibrating at 60 cycles per second. The gain is stabilized, by over-all d-c feedback, to a small fraction of one per cent. Circuits and precautions are described which have been used to adapt this type of amplifier to the measurement of contact potential drop, thermocouple electromotive force for infrared gas analysis, electromotive force of glass electrodes for pH determination, and current from capacitors resulting from leakage and absorbed charge. The relation between noise from thermal agitation and the system response is discussed.

The Problem

WHEN MAKING measurements of small direct voltages or currents, the need has been felt for a d-c amplifier, to place ahead of the indicating or recording instrument in order to measure still smaller voltages or currents.

The problem is to retain speed and stability as the gain of the amplifier is increased and the input power level is reduced.

The stability problem divides itself into gain stability and zero stability (zero output for zero input).

Retaining stability is a problem because of fluctuations of power line voltage, mechanical disturbances (shock, vibration, and tilting), magnetic fields, thermal gradients, and electric disturbances of all kinds.

Block Diagram

Figure 1 is a block diagram of the system which has been developed to meet the problem.

The conversion from direct to alternating current avoids the conventional d-c amplifier and its zero drift.[1,2,3]

The synchronous reconversion to direct current permits the use of over-all d-c feedback to stabilize the gain. By proper attention to the transmission versus frequency characteristic of the feed-back loop, notably in the output filter, in accordance with the teachings of Nyquist[4] and Bode,[5] the amplification of the a-c amplifier can be increased, without causing oscillation, to the point where the steady-state instrument reading is dependent almost entirely upon the direct current to be measured (and the value of the attenuator) and only to a negligible extent upon other factors.

The low-pass filter on the input attenuates frequencies above the response band of the system and so avoids needless overloading of the amplifier.

Circuit Variations and Applications

In adapting this type of amplifier to various applications, the circuits must be varied for

1. Voltage measurement or current measurement.
2. Low impedance or high impedance.

Figure 2*A* shows in simplified block form the series type of feedback used for voltage measurement. Because of the high amplification of the a-c amplifier, the drop across the input converter is reduced to a small fraction of the drop across the resistor *f*, as discussed later under the heading Gain Stability. This small drop means only a small current through the input converter, that is, small compared to the current through the instrument, and small enough to maintain essentially an open-circuit condition across the circuit being measured (null potential measurement).

Figure 2*B* shows in simplified block form the parallel type of feedback used for current measurement. Because of the high amplification of the a-c amplifier, the current into the input converter is reduced to a small fraction of the current through the resistor *R*. This small current means only a small drop across the input converter, that is, small compared to the drop across *R* (so that *R* and *f* form an Ayrton shunt on the instrument current), and small enough to maintain essentially a short circuit condition across the circuit being measured (null current measurement).

The terms "open-circuit condition" and "short-circuit condition" are only relative compared to the circuits being measured. Since the measured circuits vary in impedance from one application to another, ranging from something less than an ohm up to more than a million megohms, it is helpful to use more than one type of input converter circuit.

Figure 3 shows a converter circuit for medium and low impedance including an input transformer with a voltage stepup to the amplifier. One useful transformer has a voltage stepup of ten to one from each half of the primary, and has a secondary impedance of 0.6 megohm (hence a primary impedance of about 6,000 ohms) at 60 cycles, the converter frequency. Measurements check the d-c impedance looking into the converter circuit as 6,000 ohms. Figure 3 also shows details of the output-converter circuit, an output filter, the series type of feedback suitable for voltage measurement, and an input filter which does not shunt any direct current and hence is suitable for voltage measurement.

Paper 48-9, recommended by the AIEE joint subcommittee on electronic instruments and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted October 31, 1947; made available for printing November 26, 1947.

A. J. Williams, Jr., R. E. Tarpley, and W. R. Clark are all connected with the research department of the Leeds and Northrup Company, Philadelphia. Mr. Williams is chief of the electrical division and Mr. Tarpley and Doctor Clark are supervisory research technologists.

The authors wish to acknowledge the work of W. McAdam, R. E. Watson (A '46), and W. G. Amey (A '47) as covered in the appendix which supports the bare statements in the body of the paper.

Figure 1. Block diagram of d-c amplifier and measuring instrument, showing the feed-back loop

The converters permit the use of the a-c amplifier

Figure 2. *A* shows arrangement for voltage measurement using series type of feedback *B* shows arrangement for current measurement using parallel type of feedback

Figure 4 shows a converter circuit with *RC* (resistance-capacitance) coupling[6] to the amplifier. Although this arrangement provides no voltage stepup to the amplifier, it does provide the highest input impedance. With certain precautions it can be held above 100 megohms. Figure 4 also shows details of the output-converter circuit, an output filter, the parallel type of feedback suitable for current measurement, and an input filter suitable for current measurement.[6] Inspection will show that the input filter C_1 R_1 C_2 does attenuate higher frequencies which might otherwise find their way from the input to the amplifier and cause needless overloading. Since the current into the converter circuit is negligible, the d-c drop across $R_1 + R_2$ in series with the converter circuit is negligible; hence negligible drop is inserted into the measured circuit, as is desired for current measurement.

One of the early applications of the amplifier was to an urgent wartime need[7] to measure a d-c contact drop of less than 1/2 millivolt. Available deflection millivoltmeters were too critical concerning the constancy of the resistance of the leads and their connections, to give the accuracy and the fast critically damped response that was needed. The several amplifiers that were built and used on this job followed the arrangement of Figure 3 except that the input-converter circuit was as shown in Figure 4, since the range, 1/2 millivolt, was large enough not to require the step-up transformer. The input filter used two 5,000-ohm resistors, and two 1.7-microfarad capacitors. The response time of these early amplifiers was about two seconds. The stability of zero and gain was good to one division on the built-in deflection-type indicating meter. One division corresponded to ten microvolts on the input, and this stability was adequate for the application.

Another application for the amplifier, which also started from a wartime need,[8] was the measurement of the electromotive-force output of a set of differential thermocouple junctions used for infrared gas analysis (range 50 microvolts). For this job the voltage step-up transformer was used, therefore the circuit was just as shown in Figure 3. Since the thermocouples were of low impedance (50 ohms or less), the impedance of the input filter was made as low as capacitor limitations would permit. It consisted of three 2,000-ohm resistors and three eight-microfarad paper-capacitor sections which made up a unit of convenient size. This filter provides an attenuation for 60 cycles of more than 300 to 1 which experience proved to be adequate. The response time was about two seconds, and was independent of external-circuit resistance, at least up to 600 ohms. The zero was good to 0.5 microvolt without any adjustment, and fluctuations over limited periods of time were less, as will be discussed later.

Several amplifiers electrically similar to those previously mentioned are being used in the Leeds and Northrup factory for production testing. Here they are often applied as null detectors only, and for this service a varistor is switched around the deflection meter to give a semilogarithmic response and so keep the pointer on-scale and active for unbalances up to about 2,000 times the minimum detectable unbalance.

Figure 5 shows an experimental instrument, built in response to another wartime need, which has since been used to measure the minute currents from paper capacitors, and so evaluate their fitness for use in certain sensitive instruments.[6,9] The circuit is arranged for current measurement essentially as shown in Figure 4. C_1 and C_2 are polystyrene capacitors (one microfarad) to minimize spurious currents. R, R_a, R_1 and R_2 have the values 0.25, 0.25, 0.05, and 0.05 megohm, but only the value of R enters into the measurement. Since it is only 0.25 megohm, it can be made up of manganin wire to well within ± 0.1 per cent without fear of change with temperature, humidity, or time. In spite of this relatively low value of calibrated resistor, the fundamental range of the instrument is $\pm 5 \times 10^{-10}$ amperes. This is derived from a full scale voltage change across resistor f (2.5 ohm) of only 250 microvolts. Such a low voltage change is permissible because of the small zero voltage offset of the contact type of modulator.[10,11] Experience on this job indicated a value less than five microvolts. The capacitor-type modulator, as recently reported,[12,13] may have a zero voltage as great as 20 millivolts, or 20,000 microvolts; hence larger voltage changes are generally used, and the precise manganin-wire resistor must be replaced by the less precise higher valued film or composition resistors even for ranges considerably larger than the $\pm 5 \times 10^{-10}$ amperes. Figure 5 shows a dial at the left for changing to larger current ranges. Originally, this was accomplished by making the R_a resistor Figure 4 in the form of an Ayrton shunt, and by changing the position of the upper input lead on this resistor. Subsequently, it has been done by changing the position of the same lead on the R resistor, thus reducing the active part of R. The latter method has the advantage of returning the upper input lead to ground potential for all ranges.

The good zero voltage stability and low-current drain from the measured circuit (on voltage measurements) suggested the use of this amplifier for the determination of pH (hydrogen-ion concentration), especially where a high-resistance electrode is used. For example, with a commonly used type of "glass" electrode, the resistance may be 1,000 megohms at 0 degrees centrigrade; so that a current drain of only 6×10^{-12} amperes gives a drop of 6 millivolts or 0.1 pH, which may

Figure 3 (left). A circuit for voltage measurement at medium impedance, using a step-up input transformer and typical circuits for converters and filters

The input tap on *R* provides for range changing

not be a negligible error.[14] The amplifier circuit used is similar to that of Figure 3 except that the input converter circuit is the type using *RC* coupling to the amplifier as shown in Figure 4, in order to get high impedance. Calculations and measurements check the input impedance to the converter circuit to be about 160 megohms, and since the feedback reduces the voltage across this to about 160 microvolts, the current drain can be held to 1×10^{-12} amperes, from this source. Current from the grid of the first amplifier tube is not a source of error, because of the series blocking capacitor in the converter circuit, Figure 4. Precautions are required in the construction of the vibrator-type converter, Figure 9, to hold spurious currents below 6×10^{-13} amperes, but recently built converters have been giving currents not greater than 1×10^{-13} amperes. The input filter in this amplifier for pH determination consists of only one section, a one-megohm resistor and a 100-micromicrofarad capacitor. Since the voltage ranges are high (at least 0.12 volt) and since the glass electrode systems are normally shielded, this filter, which is effective only for higher frequencies, appears to be adequate. The complete circuit provides for other details such as grounding of the electrode system, compensation for asymmetry voltages in the electrode system, and compensation for temperature coefficient of the electrode system; but these details are beyond the scope of this paper.

Zero Stability

No amount of gain stability obtained through feedback will stabilize the zero. Feedback neither helps nor hinders zero stability. The general equation for any amplifier is

$$\text{Input}\times\text{gain}=\text{output}$$

For consideration of a disturbing input to the amplifier, this equation should be rewritten as follows

$$(\text{Input wanted}+\text{input disturbing})\times\text{gain}=\text{output}$$

From this equation it is clear that in the presence of a disturbing input (noise) and with the wanted input (signal) at zero, the output cannot be reduced to zero by stabilizing the gain. Disturbances may enter at points other than at the input terminals (for example, after the first stage of amplification), but they are generally measured in terms of their equivalence at the input terminals.

The use of d-c to a-c conversion, so that a-c amplification may be used, is the greatest single factor in stabilizing the zero.[1–2,6–13] This procedure avoids the conventional d-c amplifier, with its inherent zero offset and its inherent tendency to zero drift so that compensation for the zero offset can only be temporary. This zero drift results from slow changes in the tubes. Similar slow changes take place in the tubes in the a-c amplifier also, but they are attenuated by the conventional *RC* network between tubes as shown in Figure 6. The changes are further attenuated in the output transformer and finally because of the balanced arrangement of the output converter circuit are reduced to a magnitude negligible compared to the signal at this point. The effectiveness of the elimination of these low-frequency disturbances is proved by the immunity of the amplifiers to changes of power-supply voltage.

Other sources of zero disturbance are not all as easy to subdue. Such disturbances may be of an electric, magnetic, mechanical, or thermal nature. They may also be classified according to their point of entrance, namely, external to the amplifier, within the amplifier, in the d-c circuits, or in the a-c circuits. Still another classification might be made on the basis of the frequency of the disturbing currents or voltages, such as radio frequency, 60 cycles and its harmonics, or direct current with variations up to several cycles per second.

Electric Zero Disturbances

The low-frequency changes in the tubes, had they not been rendered harmless, as mentioned before, might be classified as electrical zero disturbances.

The signal, as it passes through the a-c amplifier, is in the form of a 60-cycle voltage; therefore, any 60-cycle voltage entering the amplifier other than the signal, may disturb the zero. Of course, if it has an exact quadrature phase, it will not disturb the zero; but that possibility is remote, and the only safe practice is to exclude all 60-cycle disturbing voltages regardless of phase. The power supplies for the electron tubes must be carefully filtered of 60 cycles. This applies to the heaters also, requiring that this supply must first be rectified. Heavy 60-cps currents often flow in ground paths. The voltages developed must be kept out of the meshes of the early amplifier stages. There are points of high impedance at the front end of the amplifier, and these must be provided with adequate electric shielding.

Ahead of the converter the signal is in the form of direct current; however, the

Figure 5. Amplifier (with indicator in case).

The range is normally $\pm5\times10^{-10}$ amperes, but the dial at left gives ranges for larger currents

Figure 6. Wiring diagram of amplifier for voltage

The 5-stage a-c amplifier provides adequate gain

converter will pass along a certain amount of 60 cycles as a result of the lack of perfect balance in the input converter circuit. This requires the use of a filter to reduce the 60 cycles coming in on the wires with the d-c signal. The later stages of this filter must have electric shielding against 60 cycles. This filter takes different forms for voltage and for current measurement, Figures 3 and 4. Since this filter enters partly into the path of the feed-back signal, it must be so desiged as to give proper transmission of this signal.

The whole input circuit, external and internal, must have electric shielding against very low-frequency electric effects such as the approach of a charged object (operator's hand). This is of greatest importance in high impedance circuits.

Neither side of the external input circuit may be grounded or permit of grounding. One way to meet this situation is to insulate the chassis from ground.

Although a steady direct current from the first grid cannot reach the input converter, variations of this grid current may reach the input converter, become modulated, and so cause trouble. Reduction of the absolute value of the grid current by the choice of the input tube and its bias is an obvious step. Resistance-capacitance networks between the grid and the converter, as shown in Figure 7, prevent the low-frequency grid-current variations from reaching the converter while they freely pass the 60-cps signal from the converter to the grid.

Radio frequency disturbances are common because all forms of switching on the power line generate considerable amounts of power, spread over the whole radio frequency r-f spectrum. If this radio frequency reaches the electron tubes, or even the contacts in the converter, a 60-cycle component may be developed. The r-f path may be described as electric or electromagnetic, but in any case, the protection against it is a tight, high-conductivity shield surrounding the critical tubes and the converter contacts; r-f filters must be used on all wires penetrating the shield.

Magnetic Zero Disturbances

Loops in the early amplifier stages may link with a 60-cycle magnetic field, originating in the power transformer or some external source, and so produce 60-cycle voltages of disturbing magnitude. The external circuit and early meshes of the input filter can tolerate larger induced 60-cycle voltages and from this point of view could tolerate larger loops. However, there are likely to be present slowly varying magnetic fields, and these, when loops are present, will produce low-frequency voltages which can in no way be distinguished from the signal. For voltage-sensitive amplifiers, therefore, the whole input circuit should have minimum loop size and/or be enclosed in a magnetic shield.

The early stage amplifier tubes are subject to magnetic fields, possibly the "magnetron effect," and to protect against such fields a magnetic shield is used on the first tube.

The input transformer, being a magnetic device operating at the lowest power level in the amplifier, must be well protected. It is of the core type humbucking construction, and has four concentric high permeability magnetic shields,[15] as shown in Figure 8. Figure 9 shows the vibrator-type converter. The strong field of the 60-cycle drive coil is kept away from the contacts and measuring circuit by a magnetic shield in the form of a long permeable iron skirt. In addition, all loops are kept small.

Mechanical Zero Disturbances

The item most susceptible to mechanical effect is the first stage amplifier tube. Severe table shocks formerly produced a wide band of frequencies in the output, so that there was generally enough 60 cycles to cause a disturbance. Some tubes are more susceptible than others, but a rubber-mounted socket has proved adequate to protect against all ordinary shock or vibration. This socket is also of value in avoiding oscillations from mechanical feedback.

Thermal Zero Disturbances

Current from the first grid is a function of the cathode temperature, therefore when grid current is a disturbance, cathode temperature is a factor. It is, of course, only changes of temperature which produce any effect, and even this effect can be made negligible by proper attention to minimizing the grid current effect as previously discussed under "Electric Zero Disturbances."

Thermoelectric voltages are the worst source of disturbance arising from thermal causes. There are only two methods of attack

1. To use metals giving the lowest obtainable thermoelectric power at all junctions.
2. To minimize temperature differences between thermoelectric junctions.

Since copper must be used in some places, notably the transformer primary, materials have been chosen to match copper as closely as possible. Where the circuit passes through the "button capacitors" of the r-f filters, it is preferable to drill the studs so that an unbroken piece of copper wire can pass through. It should be tacked on at one end only with a minimum amount of solder. Copper resistors are best where the exact resistance value is not critical. When necessary, manganin resistors can be built so that the copper-manganin junctions are more nearly at the same temperature. A special solder developed by General Motors[11] has a low junction potential against copper and has been found very helpful.

Steps taken to minimize temperature difference between thermoelectric junctions consist of placing the complementary junctions in close thermal proximity, and then making the paths for heat flow to and from the junctions thermally long and as nearly equal as possible.

Figure 8. Input transformer (exploded view)

The four highly permeable magnetic shields make it immune to stray fields

Gain Stability

Adequate Gain

When it is stated that the gain is stabilized by the use of over-all d-c feedback, it is the net gain which is stabilized. Referring to Figure 3, the net voltage gain is e_0/e_X.

The amplifier for infrared may be taken as an example. The resistor f was 0.5 ohm and the sum of $m+M$ was 10,000 ohms, therefore when e_0 had a steady value of one volt, e was 50 microvolts. The a-c amplifier had a voltage gain of 32,000,000 but this was multiplied by an input transformer stepup of ten and divided by a loss in the input filter, the converters, the output transformer

Figure 7. Wiring diagram of amplifier for pH

The 1,000-megohm input-grid resistors help to maintain high input impedance

Figure 10. Record of noise (principally from thermal agitation)

and output filter of about eight, so that the forward gain e_0/e_I was about 40,000,000. In particular, under the assumed condition of one volt for e_0, the error voltage $e_I = 1/40{,}000{,}000 = 0.025$ microvolt, which was negligible (one part in 2,000) compared to the 50 microvolts of e_I or the 50.025 microvolts of e_X.

A two to one reduction of the forward gain e_0/e_I from 40,000,000 to 20,000,000 (as from a severe reduction in supply voltage) would have increased the error voltage e_I to 0.05 microvolt, but this would still have been negligible (one part in 1,000 compared to the input e_X of 50.05 microvolts.

However, if the forward gain e_0/e_I had been designed to be only 2,000,000, the error voltage e_I would have been 0.5 microvolt, which is not negligible (1 part in 100) compared to the input e_X which would have been 50.5 microvolts. Furthermore, a two to one reduction of forward gain from 2,000,000 to 1,000,000 would have increased the error voltage e_I to one microvolt, which roughly would have added another 1 per cent error for a total error of 2 per cent.

The foregoing figures are given to show the importance of designing for adequate forward gain. It can be seen that if the forward gain is adequate, the error voltage is negligible and large changes of forward gain are permissible.

A simple test has been devised to determine whether the forward gain is adequate under actual working conditions. A current source (high impedance source) is connected across A and B Figures 3 or 4, of magnitude calculated to supply full scale current to the indicator M. If there is no visible change in the indicator pointer position, then the forward gain is adequate. The proof is simple. Since the indicator deflection did not change, the output from the amplifier must have taken a full scale swing, by way of compensation, and so also the amplifier input or error voltage e_I. Since this full scale swing of e_I caused no noticeable change in the indicator deflection, e_I must for all operating values be negligible; hence the forward gain must be adequate. A convenient feature of this test is the fact that the external circuit connected to the input does not have to be disturbed.

Oscillation and Its Prevention

In order to use adequate gain and not be troubled with oscillation, a single large-shunt capacitor C (with appropriate resistors), Figures 3 and 4, is used in the feed-back loop, in accordance with simple feed-back practice as set forth by Nyquist,[4] Vance,[16] Bode,[8] and others. The capacitor attenuates at the frequencies where oscillation might otherwise take place because of excessive phase shift around the feed-back loop. The single-shunt capacitor itself cannot introduce phase delay in excess of 90 electrical degrees, which is tolerable.

The capacitor is placed between the power stage and the indicating or recording instrument, so that changes in line voltage, working through the power tube, can affect the indicator only slowly, in fact, so slowly that the feedback can correct as fast as the capacitor voltage tries to change. This arrangement, therefore, dispenses with the need for a regulated power supply. It does require the use of a relatively high power output tube, because this tube must supply not only the steady-state indicator current, but the charging current for the large capacitor which, for full scale changes, may be forty times the steady state current.

The capacitor C is electrolytic in order to save size. Electrolytic capacitors are current sources.[6] If, however, the test, for adequate gain is met, then the current from the capacitor will do no harm, provided only that it does not exceed the full scale current of the indicator.

A close inspection of Figures 3, 4, 6 and 7 will disclose that the input filter enters partly into the feed-back loop. It will be noticed that the resulting phase shift is in the direction of phase advance which is the safe direction, in view of the phase delay contributed by capacitor C and its associated resistors. Fortunately, the converter-amplifier-converter system does not develop any large phase advance at low frequency, as does the simple-multistage RC-coupled amplifier without converters.

The capacitance of C should not be increased greatly above the value needed to permit the use of adequate gain, since that would needlessly slow the response. Experience shows that it is generally possible to obtain a stabilization of net gain to better than one part in 1,000 while retaining a response time of two seconds (for 99.9 per cent of full deflection after an abrupt change of input).

Overload

It is desirable to have high power capabilities in the output tube so as not to limit the charging rate of capacitor C on large changes. For the null indicator, where inputs may run to many times the normal full scale value, the power tube is called on for even more output. If it cannot supply this output, the input is not balanced and the amplifier receives a

sustained overload, so that rapid recovery is difficult.

Unwanted Feedback

The existence of the high gain in the amplifier requires that feedback, other than that intended, must be kept very low. Since this is a matter simply of good electronic engineering, details are covered by title only

1. Filter and decoupling on B supply.
2. Filter on heater supply.
3. Ground coupling.
4. Coupling from direct capacitance.
5. Shockproofing against mechanical feedback.
6. Heater temperature effects.

Phase Shift With Overload

In an electronic recorder[1–3,6] using a slide-wire potentiometer to balance, the largest unbalance does not generally exceed the minimum significant unbalance by a factor of more than 2,000. In a feed-back amplifier, however, a much larger factor may be encountered, especially during the first few seconds of warm-up. It is of vital importance that the phase of the 60-cycle signal going through the amplifier shall not be shifted with these large overloads to the point where the converter starts working in the wrong sense. When this happens the system locks itself off to one side and stays there until power is turned off. By following the circuit of Figures 6 and 7, this difficulty may be avoided.

The result is accomplished by providing for proper limiting action in the output tube and then, for increasing signals, in the driver stage, the predriver stage, and so forth.

Resistors and Instrument Used

The net gain stability can be no better than the stability of the calibrated resistors, in the feed-back loop, f in Figure 3, f and R in Figure 4. The resistor f is no problem. The advantage of being able to use wire-type manganin resistor at R for the amplifier for current has already been discussed under "Circuit Variations and Applications."

Obviously, the measurement can be no better than the indicating or recording instrument used. Most of the amplifiers made have been provided with built-in indicating instruments rated at ±1 per cent When it is desired to work more closely to the full stability available in the amplifier, an external instrument, generally of the null balance type, can be used. It can be a current-measuring instrument connected in series with the internal indicator or a potential-measuring instrument connected as the recorder shown in Figures 6 and 7.

Noise and Response Time

Thermal Agitation

Under the heading "Zero Stability" many forms of disturbance were discussed. The term "Noise" has been carried over from the language of the communication art to describe these disturbances. Most of these sources of noise are man-made, and can be reduced by precautions. However, the noise resulting from thermal agitation is of natural origin, and sets a natural limit to noise reduction. Figure 10 shows this noise as random fluctuations of the pen of a recorder connected to the infrared amplifier with the RC input filter previously described. The measured peak-to-peak noise of 0.075 microvolt is in good agreement with the 0.073 microvolt predictable from the work of Johnson,[17] Nyquist,[18] Landon,[19,21] and Jansky.[20]

Reduction of this noise in terms of input voltage equivalent can come only from

1. Reduction of the temperature of the noise-making resistance.
2. Reduction of the value of the noise-making resistance.
3. Reduction of the frequency band width of the system.

Refrigeration would be required to work on factor 1.

Factor 2, the resistance value has been varied by way of experiment. Since the noise-making resistance of Figure 10 was principally in the input filter, and since it was desired to retain the same 60 cycles per second filtering for certain applications, the 2,000-ohm filter resistors were increased to 2,500 ohms and then shunted experimentally with inductors of 22 henrys and 41 ohms d-c resistance. This reduced the noise-making resistance from about 6,240 ohms to about 360 ohms, changed the measured band width from 0.84 to 1.49 cps, and changed the measured peak-to-peak noise from 0.075 to 0.030 microvolt. This was in good agreement with the value of 0.024 microvolt calculated from the new noise-making resistance, and the new frequency

Figure 11. Effect of switching in low-frequency filtering at the recorder

The random noise is reduced, but the response time of the system is lengthened

Figure 12. Effect of switching in low-frequency filtering at the recorder in order to reduce the random noise

Sine wave inputs were used to obtain the curves. The curves are used to calculate the bandwidth of the system for each filter setting

Figure 13. Noise versus bandwidth, measured and calculated for 6,000 ohms at 300 degrees Kelvin

A reduction of band width of about 100 to 1 reduces the noise (from thermal agitation) by about 10 to 1

band width. The noise-making resistor has been further reduced in other set-ups by dispensing with the filter and by using an input transformer of greater step-up and lower primary resistance. In particular, with a 2-ohm noise-making resistance (the transformer primary resistance) and a band width of about 1 cps, the peak-to-peak noise was measured as 0.0017 microvolt compared to a calculated value of 0.0014 microvolt. Although this was working to a lower voltage level, it was not working to any lower power level.

Factor 3, the band width, was the most convenient factor to alter, since the recorder was equipped with a group of *RC* filters connected through a dial switch to reduce its speed of response,[6] and so narrow the band width of the recorder, and hence the band width of the system as shown on Figure 11. The simple *RC*-input filter was used ahead of the d-c amplifier so that its three 2,000-ohm series resistors combined to form a 6,000-ohm noisemaker. The effective band width of the system was measured by taking frequency response curves, Figure 12, squaring the ordinates, integrating under the curve, then dividing by the maximum response, which occurred at zero frequency. Calculated noise figures were plotted against band width, as shown by the straight line on Figure 13. The experimental noise figures for each filter setting were obtained from readings on the recorder chart and these values were also plotted against band width. It is interesting to note the good agreement of the measured points with the calculated curve, even to the narrowest band width measured, only 0.014 cps.

Returning to Figure 10, it will be observed that the center of the curve is only about 0.1 microvolt offset from zero. This is not the result of any bias adjustment, but simply the result of the careful construction previously discussed. Some amplifiers have had a larger offset from zero, but 0.5 microvolt appears to cover the worst amplifier under the worst condition. A goal which might be set would be to reduce the zero offset to the calculated peak-to-peak noise. As previously stated, this figure for the conditions of Figure 10 was 0.073 microvolt so the worst zero offset was greater than the calculated noise by a factor of 7. As the resistance of the circuit is reduced, the thermal agitation noise voltage is reduced,[16,11] but the zero offset can be reduced only with great difficulty, because of the thermoelectric effects. The result is that the ratio of zero offset to calculated peak-to-peak noise becomes greater and the amplifier is, in this sense, farther from the natural limit. As the resistance of the circuit is greatly increased, the thermoelectric effects become relatively less of a problem, but other problems enter. These problems are related to contact potential differences and capacitance effects, but in any case, they produce zero offset which again becomes large compared to the calculated peak-to-peak thermal agitation noise, so that again the amplifier is farther from the natural limit. The amplifier used in obtaining Figure 10 (amplifier for voltage with 6,000-ohm input filter) has the lowest ratio of zero offset to calculated peak-to-peak noise of the various amplifiers mentioned, and hence appeared to be the best example for this paper.

For some applications the zero offset is not objectionable, provided it does not vary too rapidly. In other words, these applications do not require measurement of the very low frequencies (such as a cycle per day); in brief, a true d-c amplifier is not required.

Preferred Forms of System Response

As previously explained, Figure 11 shows the response of the system plotted against time when an abrupt change of input is applied (unit step function). The different responses result from the different filter settings in the recorder, numbered 1 to 7. Figure 12 shows the response of the system plotted against frequency when sine-wave inputs are applied. The different responses result from the different (numbered) filter settings in the recorder. For each filter setting therefore, the time response has been experimentally determined, and independently the frequency response has been experimentally determined.

The amplitude at which the frequency-response curves were taken was low enough to be within the linear range, that is, below the range where limiting of any kind is significant. Limiting may occur in the amplifier or in the recording instrument which completes the system, and must therefore be considered a part of the system. Direct-deflection instruments are not inherently subject to limiting; however, in making them into recording instruments, complications enter. Photographic recording from a mirror on a suspension-type instrument is preferable. Direct-writing instruments have friction, which means they are nonlinear in a way that is most noticeable at small amplitudes. For the work here reported instead of a deflection instument, an electronically-balanced null-type recorder was used, which had a full scale balance time of 0.8 second on the No. 1 filter position. With this minimum filter setting there was definite speed limiting set by the synchronous speed of the balancing motor as apparent in the response of the recorder alone, Figure 14.[6] This limiting speed was at the rate of full scale travel in 0.62 second. A study of Figure 11 shows that the maximum speed is reduced as filtering is added (to the recorder, and hence to the system), and for filter settings 2, 3, 4, 5, 6 and 7 the maximum speed is held below the limiting value so that speed limiting is avoided. There may have been a very brief period of torque limiting but because the time constant of the amplifier input filter combined with the time constant of the recorder input filter, the recorder was called upon only for a finite value of acceleration which probably fell within the torque limit of the motor. For filter settings 2, 3, 4, 5, 6 and 7, therefore, the system was linear for any on-scale amplitude. A study of the curve for filter setting number 1, Figure 11 reveals that the maximum speed is at the rate of completing the pen travel in about 0.62 second. If the change is large therefore speed limiting will occur and the system action will be nonlinear. This complicates the analysis, also it adversely affects

the signal-to-noise ratio as will be discussed later.

Where the system is linear, it is not too difficult to apply analytical methods to relate band width to response time provided the time response has a simple analytical form. In particular, a study of Figure 11 shows that the time response of the system, especially for the large filter settings, was very close to being a simple exponential as given by a single *RC* circuit.

Another form of response commonly encountered is that of the critically damped system as given by an *LRC* circuit or the mechanical equivalent, a galvanometer with inertia, damping and suspension stiffness. It also has a definite analytical form.

These two forms of response are plotted against time in Figure 15. For comparison purposes a band width of 1 cps has been selected and the time response curves have been calculated and plotted on this basis. The simple exponential response is above that of the critically damped response up to a response of 0.72 of the full or unity value. For a null indicator or a controller, the simple exponential might, therefore, be preferable. For measurement, however, where a value must be determined to ±28 per cent or less, the critically damped form of response is faster. Countless other response forms could be considered but the one of greatest interest is the ideal response for measurment purposes. The third response on Figure 15, which we will call the terrace response, was suspected as being this ideal response, since it weights all times equally through the measuring time. The proof of this is covered in the Appendix.

Figure 15 also gives, in tabular form, the time required for the three forms to reach the half-way point and other points short of completion. Added columns give the ratio of the figures to those of the terrace response. In particular, for 0.999 completion the critically damped requires 2.32 as much time as the terrace form, and the simple exponential requires 3.46 as much time as the terrace form. For only 0.990 completion the critically damped requires only 1.68 as much time as the terrace form, and the simple exponential only 2.32 as much time as the terrace form. From these figures we might conclude that the simple exponential is not too slow for measurement to ±1 per cent.

Although the "terrace response" is an ideal response not physically attainable, it may be approached by proper circuit design.

Figure 14 shows a curve which might be thought to approach the terrace response until it is recalled that it was obtained under a speed limited condition. For smaller changes this recorder gives the same speed rather than the same balance time, as it would if it had a true linear terrace form of response. Actually, for small unbalances the speed limiting drops out and the recorder is essentially linear with a short balance time, wide frequency band, and high noise susceptibility. In spite of this, it takes extra time to measure large abrupt changes requiring nearly full scale pen travel because of speed limiting. In brief, it discriminates against the signal, which is generally large, in favor of the noise, which is generally small. Fortunately, the recorder of Figure 14 has a relatively high pen speed before limiting sets in. Sufficient recorder filtering can be added to establish operation in the unlimited or linear range. This results in a system of still moderately high speed, (2.5 seconds), Figure 11, filter No. 2, where there is no discrimination against the large signal in favor of the small noise.

Conclusions

By following certain methods and taking certain precautions as described herein d-c amplifiers can now be built with adequate stability of zero and gain to be used with precision ahead of precise indicating or recordng instruments to measure smaller voltages or currents.

Appendix

Theoretical Considerations Concerning Noise

Thermal Noise Frequency Distribution

The thermal agitation of electric charges in conductors of the input circuit, prior to the first amplifier tube, is by far the most important source of random noise within the amplifiers discussed in this report, the noise of the first tube being small in comparison. In 1928, J. B. Johnson[17] reported the first measurements of such thermal effects, which frequently are called "Johnson noise."

Figure 14. Time response of the recorder alone (with minimum filtering) to an abrupt change of input

Although the balance time is short, there is speed limiting from the motor for this filter setting

Using the second law of thermodynamics and the laws of a loss-free transmission line, Nyquist[18] has established the following equation for the frequency distribution of the thermal agitation voltage

$$E_f^2 df = 4R_f kT df \qquad (1)$$

In equation 1, k is Boltzmann's constant (1.374×10^{-23} *watt-second per degree Kelvin*), T is the absolute temperature in degrees Kelvin of R_f, and R_f is the resistive component of the impedance. The equivalent noise-making resistance in the amplifier application is the resistive component, R_f, of the impedance on the input side of the first tube, including that of the source of voltage which is being amplified.

Response of a Linear System to Thermal Noise

In interpreting the noise disturbances at the output of a linear system in terms of a theoretical noise voltage at the input, it is necessary to know the system response to given types of input signals. One approach to this problem is to determine the steady-state system response to sinusoidal voltages of unit amplitude and various frequencies. Let such voltages be impressed on a system consisting of input filter, amplifier and recorder. The amplitude of the recorder deflections as a function of frequency constitute the electromechanical frequency response $Y(f)$ of the system. The mean-square-output deflection d^2, due to input-thermal noise, can now be expressed as[18]

$$d^2 = 4kT\int_0^\infty R_f[Y(f)]^2 df. \qquad (2)$$

Equivalent Band Width

When the filtering is low-pass, as in the case of systems intended for the measurement of direct current and slowly varying signals, the maximum value of $Y(f)$ occurs at zero frequency. This value, $Y(O)$, is simply the d-c voltage sensitivity. The mean-square deflection, d^2, divided by $[Y(O)]^2$, gives the equivalent mean-square-noise voltage, e^2, at the input terminals. When R_f is substantially a constant, R, over the range of frequencies to which the system responds, division of equation (2) by $[Y(O)]^2$ gives

$$e^2 = 4kTR(\Delta f). \qquad (3)$$

The quantity Δf is known as the "equivalent band width." It may be expressed in terms of the relative frequency response, $y(f) = (Y(f)/Y(O))$, as follows:

$$\Delta f = \int_0^\infty [y(f)]^2 df. \qquad (4)$$

Analysis of Noise Traces From A Recorder

The Peak-to-Peak Method of Analysis

In the development of amplifier-recorder systems, comparison of observed output fluctuations with those predicted by equation 3 indicates whether or not all other noise source effects have been made negligible with respect to Johnson noise. Unfortunately, the mean-square-recorder deflection is not easily determined directly from the pen trace, a somewhat involved analysis being required.

Experimental studies[15,20] of the amplitudes of recorder fluctuations due to Johnson noise have led to the conclusion[20,21] that the ratio of the maximum peak-to-peak spread to the root-mean-square value may be taken as 8.0, if one excludes occasional peaks that go considerably higher. The noise traces upon which Figure 13 of this report is based were taken for ten to twenty minutes on each filter setting. They were then divided into two-inch or four-inch sections, corresponding respectively to one minute or two minutes of recording, the longer sections being used with the lower band widths. The peak-to-peak value for each section was then measured. To improve the statistics, particularly at the lower band widths, measurements were also made for new sections defined by the midpoints of the old sections. The sectioning procedure is necessary in order to leave out of account long-term drift not arising from Johnson noise. For each band width the maximum measured peak-to-peak value was then plotted as shown in Figure 13. For comparison, a graph was also plotted of the peak-to-peak values found by multiplying the theoretical rms noise of equation 3 by the factor 8, for each band width. The agreement of the experimental points with the calculated graph has been discussed elsewhere in this report. It may be added that this agreement supports the use of the factor 8.

Limitations of the Peak-to-Peak Method

The conversion of peak-to-peak values to rms values by means of a fixed ratio regardless of band width should be done with caution.[21] The lower the band width, the greater is the chance of error, since the number of peaks on a given duration of trace is smaller. Landon[21] has shown that the amplitudes of the fluctuations in the output of a linear system in response to Johnson noise at the input are distributed in size according to the normal error law. He calculates upon this basis the expectation that the peak-to-peak output voltage will exceed eight times the rms value during only 0.0032 per cent of the time, and that it will exceed seven times the rms value during 0.134 per cent of the time. It is very probable that, in the peak-to-peak measurements, the peak-to-peak spreads greater than eight times the rms values would not be observed. Also quite probably, spreads of greater than seven times the rms value would be missed at the lowest band widths, unless the observation record were considerably extended. A factor of judgment is apparently required concerning whether or not the exceptional spreads are occurring as much of the time as should be expected from their normal distribution.

Figure 15. Forms of time response

All three forms are calculated and plotted for the same bandwidth hence would yield the same noise susceptibility. The "terrace" form is an ideal form useful for comparison purposes

FORMS OF RESPONSE

Sampling Method Based Upon the Normal Error Law

An alternative procedure for determining the rms value from a noise trace, which does not depend upon the use of an assumed peak-to-peak rms ratio has been developed. This method requires that the recorder chart speed be made great enough that the widths of peaks can be measured under a magnifying glass along a few inches of trace, for various levels above and below an estimated average or center line of the noise trace. The fraction, $2p$, of the time spent by the deflection outside of two lines of separation Δd, lying parallel to and on either side of the center line, is determined. Entering with the value of p into a graph of the function

$$p = \frac{1}{\sqrt{2\pi}} \int_r^\infty \epsilon^{-\frac{r^2}{2}} dr \qquad (5)$$

as given in Figure 1 of Landon's paper,[21] where

$$r = (1/2)\frac{\Delta V}{rms}$$

and ΔV is the equivalent in volts of the separation Δd between the two chosen lines, one reads the value of r. The rms value of the noise voltage is therefore $(1/2)\Delta V$ divided by r.

One advantage of this method is that it can supply a greater amount of reliable statistical data from a small length of suitable trace than can the peak-to-peak method. This is true because it utilizes the more abundant fluctuations which exceed 7, 6, 5, and so forth, times the rms value, in order to establish the distribution-function parameter, r, which determines the rms value. The method therefore does not necessarily break down, as does the peak-to-peak method, in the case of a noise record which, because of a statistical fluctuation, does not contain any of the peak-to-peak voltage fluctuations which are as great as eight times the rms. By sampling at additional and smaller values of the line separation Δd, a consistency in the calculated rms values is established; that is, they converge to a limiting value for the rms. It may be shown that this limiting value is simply

$$rms = \frac{1}{\sqrt{2\pi} \times \text{max. slope of } P_{obs} \text{ vs } V} \qquad (6)$$

Equation 6 allows the rms value of the random trace to be obtained directly from the maximum slope of a graph of the observed fractional time, P_{obs}, spent to one side of a line parallel to the trace (and corresponding to V microvolts), plotted against V. It will be noted that in making the measurements a grid of V-lines should be drawn parallel to an estimated center line of the trace. The actual center line may be determined later, by the point $p = 1/2$ on the resulting graph. An example of this analysis upon the high speed portion of the trace shown in Figure 10 is summarized in Table 1.

Relation of Band Width to Time Response

Time Response Slope Versus Band Width

Let a represent the system response, relative to the ultimate value, as a function of the elapsed time, t, after application of a unit-step type of signal. It then can be shown that

$$\Delta f = \int_0^\infty [y(f)]^2 df = (1/2) \int_0^\infty [a'(t)]^2 dt, \qquad (7)$$

where

$$a'(t) = \frac{d\,a(t)}{dt} \qquad (8)$$

is the slope of the relative time response characteristic. This fundamental relation for linear systems was first cited, in slightly different form, by Carson and Zobel.[22] These authors emphasized the frequency response aspect of the relation, but made no use of the right-hand integral.

Band Widths for Simple Forms of Time Response

Application of equation 7 to several simple and interesting cases offers material aid

in qualitatively analyzing the effect of the shape of the time response characteristic on the equivalent band width.

The first case (Figure 15) is the simple exponential, the equation for which is

$$a(t) = 1 - \epsilon^{-\frac{t}{\tau_e}} \tag{9}$$

where τ_e is the time to reach a fraction $(1-1/e)$, or 63.2 per cent, of the ultimate value. For this case equation 7 gives the band width as

$$\Delta f = \frac{1}{4\tau}. \tag{10}$$

The second case (Figure 15) is the response which is characteristic of the critically damped galvanometer.

$$a(t) = 1 - \epsilon^{-\frac{t}{\tau_e}}\left(1 + \frac{t}{\tau_e}\right) \tag{11}$$

where τ_e is the time to reach the flex-point at a fraction $(1-2/e)$, or 26.4 per cent, of the ultimate response. For this case

$$\Delta f = \frac{1}{8\tau_e} \tag{12}$$

The last case, Figure 15, has been termed the "terrace function" type of response. It is made up of the following parts

$$a(t) = \begin{cases} 0, \text{ for negative values of } t \\ t/\tau, \text{ for } t \text{ between zero and } \tau \\ 1, \text{ for } t \text{ greater than } \tau \end{cases} \tag{13}$$

where τ is the time to reach the ultimate value. The system band width is

$$\Delta f = \frac{1}{2\tau} \tag{14}$$

Theorem: Minimum Band Width is Provided for a Given Measurement Time by the Terrace Function

Figure 15 shows that, for the same band width, the terrace type response reaches its ultimate value sooner than the exponential or critically-damped type of response. This observation suggests that conversely the terrace function may give the smallest band width of the three response types for the same measurement time, that is, time to reach the ultimate value. Since the exponential and critically-damped functions require an infinite measuring time, it is desirable to investigate the band widths for the three types of response having the same fractional measuring time, for example, the time required to reach 99.9 per cent of the ultimate response. If this time is taken as one second, the band widths are found to be: 1.727 cycles for the simple exponential response; 1.154 cycles for the critically-damped response; and 0.4995 cycle for the terrace type of response.

From these results, and from an application of the calculus of variations to the right-hand integral of equation 7, one can establish the most important characteristic of the terrace function: of all the possible response curve forms, that of the terrace function provides the minimum band width for a given fractional measurement time. It is necessary, for the general validity of this theorem, that the fractional measuring time correspond to a sufficiently large fraction of the ultimate response, so that the tail of the right-hand integral of equation 7 may be neglected from the fractional measuring time to infinity in comparison with the whole integral.

Corollary: The Terrace Function Provides the Shortest Measuring Time for a Given Band Width

Of all response functions providing the same measuring time τ, the terrace function has been proved in the foregoing section to give minimum band width, equal to $1/2\tau$, according to equation 14. The plot of band width Δf against measuring time for the terrace function is therefore the rectangular hyperbola $\Delta f \times \tau = 1/2$. Another terrace function which reaches its ultimate value in a time τ' less than τ must have a band width $1/2\tau'$, which is greater than $1/2\tau$. Also, by the theorem, all other functions which reach the ultimate value in time τ' must have band widths greater than $1/2\tau$. Therefore, any function which reaches its ultimate value in a time less than the time τ required by the terrace function cannot have the same band width, but must require a greater band width. Hence the corollary.

In practice, the infinite accelerations involved make it impossible to achieve a true terrace function response. It may be possible, however, to obtain a sufficiently close approximation, which would reduce band width, hence interference from random noise. Also, since the terrace response represents a definite minimum band width for a given measurement time, higher recording speeds can be achieved only at the expense of increased band width and noise susceptibility. In these respects the terrace function is, at least, a decidedly useful criterion against which actual responses can be compared.

Improvements in Rolling Mill Preset Screw-Down Controllers

J. D. LEITCH
MEMBER AIEE

C. A. SCHURR
ASSOCIATE AIEE

Synopsis: In the rolling mill screw-down pre-positioning control system discussed in this paper, the use of electronic-balance detectors and anticipators permits higher screw-down motor speeds without loss of accuracy in the final positioning of the rolls. The electronic-balance detectors replace polarized contact-making ammeters while balance anticipators permit the introduction of slow-down motor circuits for accurate stopping. This latter feature could not be provided so readily by the earlier control method. A new system of schedule panels on which one or more complete rolling schedules may be preset is a definite and important improvement over the earlier design. In the new panels, it is necessary to locate only two plugs for each pass per schedule while in the older method employing cords, it was necessary to locate both ends of two cords, making four connections per pass per schedule. Freedom from the complicated network of cords makes the set-up procedure more rapid and certain.

IT IS WELL KNOWN that the quality of a rolled metal product is influenced greatly by the manner in which it is rolled. All other factors being equal, a consistent control of the draft or the reduction per pass will give a product superior to that where no definite rolling schedule is followed. The accuracy of the product from a rolling mill is very important to the satisfactory operation of the succeeding mills. For example, delays can be serious at the first stand of a billet mill if there is no consistency in the separation of the rolls at the final pass of the blooming mill which feeds it.

An automatic preset screw-down controller, in which the entire rolling procedure is prescheduled by some authorized person, increases the accuracy of the final product, reduces abuse of the mill, and gives a consistently better product metallurgically.

The preset screw-down controller using differentially-driven control elements and first described in 1933[1] has found considerable favor in the control of plate mills in the brass, aluminum, and steel industries. The speed and accuracy of the control has been adequate in most cases although there has been some need for higher speeds to eliminate delay in waiting for the rolls to reach their next position, especially on return to the first pass. Any increase in the speed of the roll movement must result in loss of accuracy unless steps are taken to compensate for the additional rotational energy by adding slow-down features to the controller.

Differential Cut-Out Assembly

Before describing the improvements in the controller itself, it is necessary to show how the roll position-indicating means is tied to the screw-down drive. The differential cut-out assembly is shown in Figure 1 along with the gearing of the mill screw-down. It consists of a synchronous-tie receiver, an automotive-differential gear assembly, main and vernier rheostats, a small set-up motor, a cam-limit switch or cutout, and appropriate gearing. This cut-out assembly is a standardized unit which can be used for any rolling mill with very little change, if any.

Referring to Figure 1, any up or down movement of the mill rolls will cause a displacement of the contact arm of the main rheostat and the cams of the cam cutout. Because of the locking action of the 35 to 1 worm-gear reducer between the 1/4-horsepower set-up motor and the differential shaft *c*, the vernier-rheostat arm will not be displaced. The movement of the screw-down motor is under the control of the main rheostat and the cam cutout only. This will be described in detail later.

With the set up motor at rest, the angular movement of the rotating arm of the main rheostat is definitely related to the change in roll separation by choice of suitable gear ratio between the screw-down motor shaft and the synchronous-tie transmitter. With a given total travel, the size of the increments of roll separation is determined by the number of equally-spaced main-rheostat segments. The choices made in Figure 1 are typical of those for a plate mill. The cam cutout makes one complete revolution as the arm of the main rheostat moves from the center of any segment to the center of an adjacent segment. This movement corresponds to 0.5 inch of roll travel. With 30 segments on the main rheostat, the movement of the rolls corresponding to 29/30 of a revolution of the main rheostat arm is 14.5 inches.

With the screw-down motor idle, the 1/4-horsepower set-up motor drives the vernier rheostat, the main rheostat and the cam cutout, since the mill holds the shaft *a* fixed through the synchronous-tie motors. Under this condition shaft *b* rotates at the same speed as shaft *c* but in the opposite direction. With 20 segments on the vernier rheostat, as shown in Figure 1, the maximum movement is limited to 19/20 of a revolution of both the rheostat arm and cam cutout, and also 19/20 of a segment on the main rheostat. Thus, operation of the set-up motor moves the main rheostat arm and the cutout cams backward or forward a fraction of a main increment. The amount of this fractional displacement is preset on the schedule panel which controls the movement of the setup motor. Such a schedule panel is a vernier adjustment in the final positioning of the rolls. The

Paper 48-11, recommended by the AIEE industrial control committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26-30, 1948. Manuscript submitted November 19, 1947; made available for printing December 8, 1947.

J. D. Leitch and C. A. Schurr are both with the Electric Controller and Manufacturing Company, Cleveland, Ohio.

Figure 1. Differential cutout and associated gearing

One inch roll travel = 15 revolutions of screw-down motor
= 15 × (20/75) = 4 revolutions of synchronous-tie motors
= 4 × (34/36) × (9/34) × 2 (differential factor
= 2 revolutions of cut-out shaft
Therefore 1 revolution of cam cut-out shaft = 0.5 inch roll travel
= One segment on main rheostat
Therefore 1 segment on vernier rheostat = (0.5/20) = .025 inch roll travel
Roll travel under automatic control = (29 × 0.5) + (19 × .025) = 14.975 inches

main rheostat is used in conjunction with the cam cutout in controlling the direction and final position of the screw-down motor in accordance with a preset schedule on the main schedule panel. The vernier schedule panel controls the final position of the setup motor through the vernier rheostat. Thus while the main schedule panel may call for 1.5 inch roll separation, the actual separation may be more than this by the amount of the initial displacement of the main rheostat introduced by the movement of the setup motor. This vernier adjustment increases the range of roll travel under automatic control from 14.5 inches to 14.975 inches, the difference being 19/20 of 0.5 inch as provided by 19 increments on the vernier rheostat.

The purpose of the differential gearing and the setup motor is fundamentally that of reducing the number of schedule selection points on the schedule panels. Without the differential gearing, it would be necessary to provide a total of 599 points to cover a range of 14.975 inches in increments of 0.025 inch. With the differential gearing the number of schedule points is reduced to 50, 30 on the main panel and 20 on the vernier. For complete flexibility, it must be possible to connect any one of as many as 25 passes to any one of these points. The number of points on the new schedule panel is reduced from 14,975 to 1,250 per schedule. Actually 25 passes are rarely used, eleven to twenty-one being commonly provided.

Electrical Interpretation of Roll Separation

Referring to the upper part of Figure 2, a 16-segment rheostat is shown along with a 13-pass schedule panel and a thirteen-step ratchet or stepping relay. Fifteen identical resistors are connected in series across the 16 segments of the rheostat to form a potentiometer. A 115-volt a-c supply is connected across these resistors in series with two adjustable resistors. By suitable choice of the 15 resistors and adjustment of the external resistors, it is possible to provide $2^1/_2$ volts between adjacent segments of the rheostat. The 16 segments are connected to 16 horizontal conductors which make up part of the schedule panel.

The stepping relay has a level for the main schedule panel and another for the vernier panel. Its operating coil is so connected in the control circuits that on completion of the roll travel to any preset position, it automatically steps its con-

Figure 2. Position indicator, electronic balance detector, and anticipator

Figure 3. The cam cut-out

tact arm forward to the next stationary contact or pass number. In the case of the setup-motor control, this new position of the stepping-relay arm on the vernier level immediately results in the vernier rheostat being driven to the position called for by the vernier schedule panel. At the same time the stepping relay, through its main level, sets up the necessary circuit for the movement of the screw-down motor to its next position. Such movement does not occur until the operator presses the operating push button after the metal has left the rolls at the completion of the preceding pass.

In addition to the 16 horizontal conductors on the schedule panel, there are 13 vertical conductors, one for each of the 13 passes provided by the stepping relay. Insertion of a plug at any point of intersection of a horizontal and vertical conductor connects them together electrically and schedules some particular pass to a definite roll separation. For example, if number 3 pass is plugged in at $6^1/_2$ inches on the main schedule panel and at 1/32 inch on the vernier panel, the screw-down motor will drive the rolls to give a separation of $6^{17}/_{32}$ inch after the operator presses the operating button for the third pass.

Assuming the schedule panel plugged in for all 13 passes, each position of the stepping relay will electrically connect its contact arm to a specific segment on the rheostat depending on the position of the plug for that pass. It will be shown later how the screw-down motor and the setup motor are brought to their final stopping positions with the main and vernier rheostat arms at the centers of segments.

The electric potential at the rheostat arm is determined by the position of the mill rolls while the position to which the rolls are to move on the next pass determines the potential at the arm of the stepping relay. Thus a signal voltage exists between the arm of the rheostat and that of the stepping relay. The magnitude of this potential difference is directly proportional to the required distance of roll travel while its phase relative to the 115-volt a-c supply, indicates the required direction of travel.

Phase-Sensitive Balance Detector

The phase-sensitive balance detector consists primarily of two thyratrons with a directional relay in the plate circuit of each tube as shown in Figure 2. A transformer *T2* supplies power to each thyratron plate in series with the coils of these relays. Since the transformer feeds the plates of both tubes in parallel, the voltages on the plates of both tubes are in the same phase. A second transformer *T3* supplies the grids of both thyratrons, in series with the secondary of transformer *T1*, with a lockout voltage 180 degrees out of phase with the plate voltages. This lockout voltage is of sufficient magnitude to prevent either tube from conducting when no signal voltage is present at the primary of the input transformer *T1*.

Suppose an a-c signal voltage appears at the primary of *T1*. The voltage at the secondary of this transformer can be considered as two equal voltages from the center tap of the transformer to either end of the secondary winding, these voltages being 180 degrees out of phase with each other. Since one half of the secondary winding of *T1* is in series with each grid, the voltage from the center tap to either end of the transformer winding will add vectorially to the common lockout voltage. In the grid circuit of one of the two tubes this secondary voltage will add to the lockout voltage in the same phase to prevent conduction of this tube. In the grid circuit of the other tube the secondary voltage of *T1* will be 180 degrees out of phase with the lockout voltage and of sufficient magnitude to more than cancel the lockout voltage and cause the tube to conduct. This is true even though the signal voltage appearing at the primary of *T1* corresponds to only one segment or $2^1/_2$ volts because of the turns ratio of transformer *T1*. With one of the tubes conducting, half-wave rectified current will flow through the coil of one relay but not the other. These relays control the direction of movement of the drive.

If the phase of the input voltage is reversed calling for motion in the opposite direction, the opposite tube will conduct. The circuit is thus sensitive to the phase of the input signal voltage relative to the common supply voltage. Closure of relay *UR* or *DR* sets the motor in motion in such a direction as to reduce the signal to zero.

The earlier method of sensing the required direction of travel employed a polarized contact-making ammeter connected across a d-c signal voltage. With direct voltage across the potentiometer and with high ohmic value external adjusting resistors, the voltage per segment was about 0.5 volt. Because of the low resistance of the ammeter shunt, the change in current through the ammeter coil, with change in the number of segments bridged by it, was small. Thus an ammeter sufficiently sensitive to provide contact when bridging two segments could have a coil of adequate thermal capacity to carry the current when bridging the maximum number of segments. The use of a balance detector of such low impedance as an ammeter does not lend itself readily to the introduction of any balance anticipatory control. The low voltage provided per segment necessitates the maintenance of clean contact surfaces on the stepping relay, the main and vernier rheostats, and the schedule panel plugs. In spite of these disadvantages, the use of a contact-making ammeter has proved highly satisfactory on a number of installations.

Electronic Balance Anticipator

Referring to Figure 2, the balance anticipator, as the name implies, is a means of interpreting how closely the

Figure 4. Typical screw-down motor circuit

Figure 5. Differential cutout and the old schedule panel

drive is approaching the pre-scheduled position. The anticipator consists essentially of a full-wave rectifier, a potentiometer, a thyratron, a slow-down relay and a phase shifter. The plate of the thyratron is supplied with alternating current from the secondary of transformer *T4* in series with the coil of slow-down relay *SD*.

The grid circuit has two voltage sources, one a-c and the other d-c, connected in series and adding up to the voltage e_g. The direct voltage is obtained by rectifying the output voltage of the signal transformer *T1* with a full-wave selenium rectifier. This rectified voltage is connected to the ends of an adjusting potentiometer *R1* in such a way that the grid of the thyratron will be negative with respect to the cathode. The alternating voltage in the grid circuit is the voltage appearing across the phase-shifter resistor. It is of small magnitude and it functions to provide a more definite operation of the slow-down relay, by insuring full half-wave conduction of the thyratron.

The magnitude of the direct voltage in the grid circuit varies with that of the signal voltage. The voltage from the positive end of resistor *R1* to the position of the adjusting tap will tend to prevent the thyratron from conducting. Thus with a large a-c signal voltage at the primary of the transformer *T1*, corresponding to a movement of several segments, and with the adjustable tap on *R1* set somewhere near the negative end, the anticipator thyratron will not conduct and the slow-down relay will not close. As the rheostat arm approaches the balance segment the signal voltage will decrease in magnitude until the direct voltage in the grid circuit will permit conduction as a half-wave rectifier, closing relay *SD*. If the adjustable tap on resistor *R1* is located at the positive end, the thyratron will conduct and the *SD* relay will close. Thus, by adjusting the position of the tap on resistor *R1*, the *SD* relay can be made to close at any desired number of segments from the balance segment.

The a-c signal voltage is rectified to eliminate the effect of phase reversal with different directions of motion but with fixed phase of plate voltage.

The ingot or slab is usually short during the first few passes and the actual rolling time is of the order of a second or two. When the screw-down motor stops, the setup motor automatically starts, to establish the vernier displacement of the cutout assembly. If the operator should immediately "enter" the metal between the rolls, it is quite possible that the pass might be completed before the setup motor comes to rest. If the operator should then start the screw-down motor at the instant the metal leaves the rolls, the screw-down motor might be delayed in reaching its stopping position until the setup motor has established the vernier adjustment. This delay occurs only in those cases where the vernier-schedule panel calls for a long movement of the vernier rheostat and the main schedule panel calls for little or no change.

By greatly increasing the speed of the setup motor the delay can be eliminated entirely. The electronic-balance anticipator enabled this to be done without loss in accuracy. It permitted an increase in speed of the setup motor from 400 to 1,750 rpm giving a reduction in setup time from 4 to $1^1/_2$ seconds for maximum travel of the vernier rheostat. The control of the set-up motor is simple because of the constancy of the inertial and frictional characteristics of the system which it drives. By suitable adjustment of the anticipator along with the armature-shunt resistor which it controls, and by proper selection of the final dynamic-braking resistor introduced at balance, it is very easy to stop the setup motor consistently at the center of the vernier-balance segment.

Function of the Cam Cutout

The cam cutout is essentially a cam-limit switch having four separately adjustable cams. It is so geared that its cams revolve through one-half revolution while the main rheostat arm moves half a segment. The cutout is used in conjunction with the main rheostat in slowing down and stopping the screw-down motor in the following manner.

When the rheostat arm makes contact

Figure 6. Screw-down controller with contact-making ammeters

with the final or balance segment, the electronic-balance detector opens one of the two directional relays. This leaves the directional contactors under control of the cam cutout. The position of the cams at that instant is shown in Figure 3. Assuming the screw-down motor is driving the rolls in the down direction, the down-contactor cam has just closed its associated contacts to by-pass the contacts of the *DR* relay which are now open. The down contactors on the controller will thus be held closed until almost half a cam revolution later. During this half revolution of the cam cutout, two additional cams close their associated contacts in sequence to provide two steps of slow-down prior to opening the down contactors and setting the brake. A similar sequence occurs in the up direction, this time with the up-contactor cam and the same two slow-down cams. In the event of overtravel of the rolls, the motor will be "plugged" under the control of either the up or down cam according to the direction of motion.

For accurate final positioning, it is necessary to bring the motor to a predetermined speed before the cam cutout takes over control of stopping. The electronic-balance anticipator has proved valuable in improving the accuracy of stopping the screw-down motor by introducing slow-down circuits prior to reaching a balance on the main rheostat. Because of the need for higher speed in moving the rolls to the first pass position, it has been found worth-while to add a second balance anticipator so connected that it is effective only on the first pass.

Figure 4 shows a typical plugging-reversing controller for a single motor screw-down drive using a d-c series mill-type motor. Assuming two steps of anticipatory control the sequence of contactor operation during the slow-down and final stopping might be as follows.

The first and second anticipators close contactors *1SD* and *2SD* in sequence to strengthen the field giving two steps of slow down. At balance the electronic-balance detector opens the acceleration contactors *1A* and *2A* to reduce the voltage on the motor armature and further reduce the speed. The cam cutout takes over the control to insert two steps of armature shunt resistance by closing contactors *1AS* and *2AS*. Finally as the rheostat arm approaches the center of the balance segment, the directional cam opens the directional contactors and the slow-down contactors to permit the series brake to set.

Both the inertia and friction of the system may be changed when new rolls or guides are installed. It is a simple matter to adjust the controller for such changes by altering the position of the tap on resistor *R1* of the balance anticipators.

Figure 5 shows a 2-schedule panel of old design with a schedule selector switch and two 25-point 6-level stepping relays. The differential cutout assembly is shown mounted directly below the schedule panel. The use of a double schedule panel permits setting up two different rolling schedules. In changing from one to the other it is necessary only to move the schedule-selector switch. The double schedule panel has been found useful in those cases where the schedule is changed quite frequently, the change being made on one while operating the mill on the other.

The two groups of receptacles at the top of the panel are used in selecting the total number of passes after which the stepping relays return to pass number 1.

The main disadvantage to this form of schedule panel is the difficulty in following the cords in checking a preset schedule. It, however, has the advantage of occupying a small space. This is accomplished by limiting the number of receptacles on the assumption that it will not be necessary to use more than a few for any one increment in taking care of all the pass positions required in actual operation.

Figure 6 shows a typical factory-assembled screw-down motor controller and the associated relay panel for automatic preset operation. The two polarized contact-making ammeters are located at the top of the relay panel.

Figure 7 shows the new design of schedule panel for a single schedule. The larger panel with 30 increments is the main panel while the smaller is the vernier panel with 20 increments. It will be observed that the rolling schedule may be checked at a glance. The final pass selector is shown plugged in at pass number 15.

Figure 7. New schedule panel

Figure 8. Electronic balance detectors and anticipators

Figure 9. Operator's desk

The electronic-balance detectors and anticipators are shown in Figure 8. Two balance detectors, one for the main and the other for the vernier, replace the two contact-making ammeters shown in Figure 6. Three balance anticipators are shown, one for the set-up motor and two for the screw-down motor. All three anticipators are identical as are the two balance detectors. The adjusting potentiometers are shown below the slow-down relay on each anticipator.

The control desk of a plate mill screw-down controller is shown in Figure 9. In this mill both the vertical and horizontal rolls were controlled by automatic preset screw-down controllers while the front and rear side guards were automatically moved in and out under the control of short-travel limit switches. The six dials at the rear of the control desk are "Productimeters" which give the separation of both the edger and the horizontal rolls along with the position of the side guards. The Productimeters are driven by "selsyn" receivers governed by transmitters tied to appropriate parts of the mill.

Operation of the Screw-down Controller

As long as a-c power is on the synchronous-tie motors, the mill rolls and the differential cutout will be held in synchronism even though the rolls are moved under manual control beyond the range of the schedule panel. In the event of loss of a-c power the a-c electrical interlocking, which normally would stop the controller, can be by-passed to permit operation of the mill by manual control. In such an event it will be necessary to resynchronize the mill and the differential cutout before again rolling under automatic control.

A cold ingot or a cobble may make it necessary to depart from the preset rolling schedule. A separate master switch is provided for conventional manual operation. It is so connected in the circuit that when it is moved from the off point, it takes over complete control of the screw-down motor, and the automatic preset controller cannot operate unless the master switch is in the off position.

It may happen that after having operated the screw-down manually for a few passes, it is desirable to return to the preset schedule. In this case it is necessary only to return the master to the off point, step the ratchet relay forward to the required pass by a push-button provided for this purpose, and press the operating button. The rolls will then be moved to the preset position for that pass, and the rolling can be continued under preset control.

Service Restoration With Automatic Air-Break Switches

KENNETH N. REARDON
MEMBER AIEE

AUTOMATIC pole top air switches for more than twenty years have played an important part in the operation of the 25,000-volt system of the West Penn Power Company. Nearly one hundred are now in service; they promptly, reliably and economically sectionalize lines, isolate faulted equipment, and transfer power loads from one source to another. No definite limit has been set for the size of loads controlled by automatic air switches; the largest transformer bank to date is of 3,000-kva capacity.

Control circuits have been kept simple and direct; operating procedure is such that, except for special cases, no close co-ordination of timing is required with associated automatic reclosing circuit breakers. Control schemes and the philosophy of their application are presented in this paper.

General

Automatic air-break switch installations may be classified into five general types descriptive of their functions; namely, by-pass, grounding, isolating, transfer and sectionalizing.

Figure 1. Operation lockout relay used in transfer and sectionalizing control

Type 1—By-Pass

This function is accomplished by a single air switch normally open and relayed to close when events make such action desirable. It is used to by-pass a station which has been relayed out of service because of trouble in the station itself. Occasionally in an area of heavy load concentration, a network must be strengthened by tying together automatically a pair of lines which have been separated by a substation bus fault.

Type 2—Grounding

This function finds perhaps its sole application in the protective relaying of a transformer bank tapped to a transmission line with automatic circuit breaker protection at the distant ends of the line. The grounding air switch is installed on the line side of the transformer bank; between it and the line there is usually installed an automatic opening air switch (especially if the transmission line has other loads connected to it). Protective relays, operated by a fault in the bank, trip open the local load side circuit breaker and close the line side grounding air switch. The line promptly trips at its distant ends and the transformer bank line side air switch opens under a no-load condition. The bank is thus isolated and the transmission line may again be placed in service.

Type 3—Isolating

The function of this single air-switch type is to isolate a faulted line or transformer bank. The isolation of a transformer bank has been described in the foregoing discussion of the grounding switch function. An application is found also in the automatic disconnection of a branch line from an important tie line. The air switch is normally closed and opens when the tie line is relayed out of service; usually the opening is delayed until at least one test has been made of the entire circuit. The disconnection of the branch may make it possible to restore the main line to service.

Type 4—Transfer

This application consists of two automatic air switches installed in close proximity. One is normally closed and one is normally open; a transformer load is connected to the bus between them. A source of power is obtainable through either of the air switches; neither source is considered "preferred" and the station will remain connected to the source from which it is receiving power until that source fails, whereupon it will transfer to the other source of power if that second source is available. If a permanent fault occurs on the bus between the automatic air switches, a transfer operation will take place and thus the bus will receive one test. After this one test both air switches will stand open until manual switching is performed. With both switches open and the fault thus isolated, all other sections of the line can be energized from their respective sources of power.

Type 5—Sectionalizing

The sectionalizing installation may consist of one switch strategically located at a selected point in a long stub feeder or in a tie line between two substations. It may take the form of two air switches located at widely separated points so as to break the circuit into three sections. The

Paper 48-13, recommended by the AIEE relay and substation committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted November 10, 1947; made available for printing December 26, 1947.

Kenneth N. Reardon is engineer of switchgear with the West Penn Power Company, Pittsburgh, Pa.

The author expresses his appreciation to H. A. P. Langstaff (F '43), electrical engineer for the West Penn Power Company, Pittsburgh, Pa., for his advise in the writing of this paper and for his direction in the development and application of the automatic air switch installations; also to L. J. Prasky, assistant engineer of West Penn Power Company for his skill in drawing the many illustrations.

Figure 2 (left). Selector relay used in transfer control

Figure 3. Transfer type station *N*

most common type of sectionalizing air switch application consists of two air switches installed in a line with a bus between them to which a transformer load is connected. A source of power is available from each end of the line. Both air switches are normally closed and both are relayed to open simultaneously when the through line is de-energized.

Power will always be restored to the substation bus from the first line section which is re-energized; the sections will be closed together if both become energized. Two of these automatic sectionalizing stations may be readily connected in series between two power sources with a third power source brought to the section of line between them. Reliable operation can be obtained even without that third source of power, although restoration of power to the mid-section will be less prompt.

Summary of Functions

The first three functions, by-pass, grounding and isolating are straightforward applications of automatic control which invite the attention of the application engineer. The remainder of this paper will be given over to the analysis and exposition of the other two functions transfer and sectionalizing because of the predominance of their use. They have proved to be effective and economical methods of service restoration.

Salient Features of Application

L. F. Hunt of the Southern California Edison Company has stated in his excellent paper[1] that:

"Simplicity is of paramount importance when designing and laying out protective relay circuits. These circuits are called upon so infrequently to operate that they should be more reliable than the apparatus or lines they protect. Many fancy conditions and requirements that are requested from the designers of circuits generally cause more fault tripping and thus become less reliable. When all the extra gadgets are left out of a protective system, the simple system operates so satisfactorily that the reasons for its good operation are generally forgotten."

Simplicity is commendable also in the application of functional relaying; the operation of automatic air switches lies in that category. Frequently the application engineer is burdened with control specifications which demand that the circuits cope with the unusual rather than the usual situation. Consideration of probabilities will result in circuit simplification without sacrifice of reliability.

The West Penn Power Company has built into the control of the automatic air switch that intelligence which would be expected of a well-trained substation operator. At the transfer station, the closed air switch is opened promptly when power fails, provided that the second source of power is available; the air switch to this second source is closed promptly and the substation bus again has power after a delay of about six seconds. At the sectionalizing station, both normally closed air switches are immediately opened upon loss of power and are closed promptly as soon as the individual lines become energized. Within ten seconds, the station bus again has power.

Lines are not tested prior to the action of the automatic air switches. Since line faults are frequently of a temporary nature, it is true that the air switches operate more often than necessary; there is certainly no harm in thus exercising the mechanism. When the line fault is of a permanent nature, there is definitely a gain in the speed of restoring service. If air switch action is delayed until one test is made, five seconds will be lost in restoring service to the transfer type of station and thirty seconds will be lost in restoring service to the sectionalizing type of substation. (Thirty seconds represents the time between the first and second tests.)

General West Penn Power Company Operating Conditions

William C. Bowen of West Penn Power Company and Edward Beck of Westinghouse Electric Corporation recently wrote[3] that:

"The 25-kv system of the West Penn Power Company is practically an overhead network. It feeds 374 step-down substations supplying customers and distribution loads and also serves directly a number of industrial customers. The system is located in regions where lightning storms are frequent and usually severe."

The 25-kv system is composed of lines ranging from 5 to 25 miles in length and is closely coupled with a strong 132-kv superimposed transmission system. The out-of-synchronism problem does not arise when sectionalizing air switches open and they can be reclosed without recourse

to synchronism check relays. The four components of an automatic air-break switch installation are (1) a means of detecting that a service abnormality exists; (2) a relay control scheme to operate the air switches according to a predetermined plan; (3) a source of power for operating the air switches; (4) the air-break switch itself.

Potential transformers or power transformers of 10-kva capacity are used to detect service abnormality. Absence of voltage and presence of voltage are the criteria which exercise control over both the transfer and the sectionalizing type of automatic air-break switch installation.

The relay sequence is simple and is composed of time delay over-voltage and under-voltage relays combined with an operation lock-out relay and a latch type selector relay.

A 48-volt storage battery supplies the source of power for operating the air switches of the sectionalizing type of installation; batteries of higher voltage are used if installed at the air-switch location for other service. A single-phase 10-kva transformer connected to each of the two lines provides the power source for the transfer type of installation.

The air-break switch itself is a standard production item and need not be discussed in this paper. Motor operating mechanisms are used by West Penn Power Company entirely (the grounding type of air switch is, however, spring operated).

It has been stated previously that a permanent fault on the bus of either the sectionalizing or of the transfer station will result in both air switches opening and remaining open until manual switching is performed. Figure 1 shows the 2-element operation lock-out relay by which this important feature is accomplished. One element is a toggle-type relay; the other element is a timing relay. Operating coil *TO* is energized briefly when an air switch is traveling from the open to the closed position; by instantaneous toggle action, contact *TO1* opens and contact *TO2* closes. Contact *TO1* is in the closing circuit of one of the air switches; the air switch cannot automatically close unless that contact is in the closed position. Contact *TO2* completes the circuit of the timing element which is supplied potential from the line controlled by the air switch which has caused the toggle element to operate. At the completion of the timing period a contact *M* is made which causes the toggle relay to reset provided that (in the sectionalizing type of application) the air switch which operated the toggle relay is closed, or provided that (in the transfer type of application) either, or both, of the air switches is closed. If the line becomes de-energized during the timing period, the timer will instantly reset and again start its full timing period when the line is energized; the line must remain continuously energized throughout the timing interval be-

Figure 7. Control diagram for air switch *A* of Figure 6

Control diagram for air switch *B* is similar except apply letter *B* in place of *A* throughout. Auxiliary switches same as in Figure 4

Figure 9. Service restoration schedule for permanent fault on section *LN* of Figure 6

fore a reset action can take place. Another relay that merits description is the electrically-operated electrically-reset latch type relay used as a selector in the transfer type of application. It is shown in Figure 2 and operates as follows:

When coil *BC1* is energized, contact *BC1* closes and latches closed. If coil *BC1* and coil *AC1* are simultaneously energized, contact *BC1* only will be closed because coil *BC1* controls the movement of the armature, whereas coil *AC1* merely unlatches the armature. The purpose of this relay is to prevent both air switches from closing if both lines become energized simultaneously after having been both de-energized by a total power interruption involving both circuits (see Figure 3). It also aids in the lock-out condition

Figure 10. Service restoration schedule for permanent fault on bus of station N of Figure 6

that takes place when a fault occurs on the bus between the air switches.

To simplify the control diagrams in this paper, the motor circuit of the air switches has been omitted; closing and opening contactors only have been shown, with an associated auxiliary switch that supplies a detail necessary for clear understanding of the circuit. A 4-pole double-throw manual-automatic transfer switch and two switchboard "Open-Close" control switches have likewise been omitted as being not essential to the description of automatic operation.

Operation of the Transfer Type of Automatic Air Switch

Figure 3 is an illustration of a 25-kv automatic transfer station. It is installed where the load is that of an industrial town or is one of a critical nature such as a gaseous mine ventilating fan or man hoist. Air switch *A* is shown closed, air switch *B* is shown open; both air switches are equipped with 115-volt a-c motor

Figure 11. A 3-source network with two sectionalizing type stations, *N* and *P*

mechanisms. To each line there is connected with live line clamps (no fuses) a 10-kva 25,000 125-volt transformer. The transformer on line *WA* acts as a voltage detector; it also supplies power to open switch *B* and to close switch *A*. The transformer on line *RB* performs like potential detection service and supplies power to open switch *A* and to close switch *B*. Stations *W* and *R* represent power sources to the lines *WA* and *RB*.

Loss of power supply from line *WA* results in the opening of air switch *A* and the closing of air switch *B;* within six seconds, power is thus restored to the substation bus. The substation then remains connected to line *RB* until an interruption occurs on that line whereupon it will transfer to line *WA*. The station always remains upon that line from which it is receiving power and always transfers to the other line when power is interrupted provided that the other line is energized.

When air switch *B* closes it energizes a lock-out relay which makes air switch *A* nonclosing until the lock-out relay resets. The lock-out relay will reset if after the closing of air switch *B*, line *RB* remains energized for five consecutive seconds. If line *RB* becomes de-energized as soon as air switch *B* closes, it is definite evidence that a fault exists upon the bus between air switches *A* and *B*. That being the case, as soon as line *WA* is re-energized, air switch *B* will open. Both air switches are now open and remain open. Line *WA* and *RB* can both be re-energized to supply power to other customers. Air switch *A* cannot reclose because the aforesaid lock-out relay has not reset. Air switch *B* cannot close again because when it tripped it opened its own closing circuit through contacts *BC1* of the selector relay (Figure 2). It should be noted that when a fault occurs on the bus between the air switches only one test is made. When line *WA* is the original source of power to the bus, the test is made from line *RB*. Line *WA* is not subjected to a second interruption nor is line *RB* after it has been re-energized.

Figure 4 is a schematic diagram of the control sequence which takes place when the substation is transferred from line *WA* to line *RB*. Events take place in the following sequence:

A fault occurs on line *WA* and the breaker at station *W* opens, de-energizing the line. Time delay undervoltage relay *AUV*, connected to the *WA* line potential transformer at *AX* and *AY* closes its contacts within a second and completes the circuit to the opening contactor *AO* of switch *A;* it also completes a circuit to coil *BC1* of the selector relay. Auxiliary contact *AO* maintains these coils energized until the air switch is nearly full open at which point the auxiliary switches *Aa* both open. Auxiliary switch *Ab* closes when the air switch is open and completes a circuit through contact *BC1* (which has just been closed) and contact *SGRA-TO1* to the closing contactor *BC* of air switch *B* and to the operating coil *TO* of lock-out relay *SGRB*. Auxiliary

Figure 12. Service restoration schedule for temporary fault anywhere on network of Figure 11

Figure 13. Service restoration schedule for permanent fault on bus of station *N* of Figure 11

contact *BC* keeps the contactor coil energized until air switch *B* is in the fully closed position. The station has transferred to the line *RB* and will remain there until automatically or manually returned to line *WA* at a subsequent time. While air switch *B* is closing, the operating coil *TO* of lock-out relay *SGRB* is energized briefly through auxiliary switch *Ba/b* which is closed only when the air switch is in motion. The toggle relay instantly opens contact *TO1* in the closing circuit of air switch *A* (see Figure 5) and closes contact *TO2* (of Figure 4) completing the circuit of *SGRB* motor *M*. If line *RB* remains energized for five seconds, this motor will close its contact *M* and energize reset coil *TR* of relay *SGRB* which will open contact *TO2* and close contact

Figure 14. Service restoration schedule for permanent fault on bus of station *P* of Figure 11

TO1 thereby restoring the lock-out relay to normal operating condition.

If line *RB* does not remain energized for five seconds, as would be the case if the fault is on the bus of station *N* instead of on line *WA*, relay *SGRB* will not reset. Line *WA* next becomes energized by the closing of the breaker at station *W*; by referring to Figure No. 5 it can be seen that under-voltage relay *BUV* with its contacts closed, energizes coil *AC1* of the selector relay and the opening contactor *BO* of air switch *B* whereupon the air switch opens. It cannot close again automatically because contact *BC1* is open. Air switch *A* cannot close again automatically because contact *TO1* in relay *SGRB* is open.

Both air switches are now open and neither can perform any further automatic action. An operator is dispatched to the station, clears the fault from the substation bus, and closes one of the two air switches to restore service to the substation. After five seconds, the lock-out relay will reset regardless of which air switch has been closed by the operator. At all of these stations a four pole double throw automatic-manual transfer switch is provided. The operator throws this switch to the manual position in order to operate the air switches electrically and restores it to the automatic position upon leaving the station in normal operating condition. Manual mechanical operation of the air switches is possible also if the need arises.

Operation of the Sectionalizing Type of Automatic Air Switch

Figure 6 is an illustration of a 25-kv automatic sectionalizing type installation. It is used where there is a load of a critical nature connected to a tie line between two substations. (The tie line aspect makes this installation different from the transfer type station of Figure 3 which has two independent sources of power.) Air switches *A* and *B* are both normally closed and both are equipped with 48-volt d-c motor mechanisms. A potential transformer (or a 10-kva 25,000 125-volt transformer) is connected on the line side of each air switch with live-line clamps (no fuses). The transformer supplies voltage to an over-voltage relay and an under-voltage relay. The air switches are operated by a 48-volt battery.

Both air switches open within three seconds time after line *LK* is de-energized because of a line fault. Breaker *C* at station *L* and breaker *D* at station *K* close automatically and test line sections *LA* and *KB*. The unfaulted section will remain energized and the corresponding automatic air switch at substation *N* will close within three seconds, restoring power to the bus of station *N*. If the other section of the line is subsequently re-energized, the second air switch at substation *N* will close and the entire line will be restored to normal. If the fault is permanent in nature, the second air switch will not close. Substation *N* will always obtain power from the line section which is energized first; the entire line will be restored to service if both sections prove to be good.

Figure 15. A 2-source line with two sectionalizing stations in series

If a fault occurs on the bus between the automatic air switches, both will open. Air switch *A* will close as soon as the section *LA* is energized and will again open when the circuit breaker at *L* again trips. Air switch *B* will likewise close and open. Both air switches will then remain open until they are closed by an operator. This lock-out is accomplished by the relay shown in Figure 1; after having been closed electrically, the air switch cannot at a subsequent time automatically close unless it has reset its lock-out relay by remaining closed for five seconds.

Figure 7 is the schematic control diagram for automatic air switch *A*; the control diagram for automatic air switch *B* is exactly the same. The control circuits of switch *A* are entirely independent of those for air switch *B*. In that respect this control scheme differs from the interlocked control of the air switches of the transfer type of installation (see Figures 3, 4 and 5). A description of the operating sequence which takes place when air switch *A* is called on to operate is applicable also to air switch *B*.

When line *LK* is de-energized, over-voltage relay *AOV* (Figure 7) opens its contacts *AOV* and under-voltage relay *AUV* closes its contacts *AUV*. These

two relays are independent time delay relays and in order to make certain there will not be a control conflict caused by contacts of both relays being simultaneously in the closed position, precedence is given to the under-voltage relay *AUV*. Its contacts *AUV* energize a 48-volt auxiliary relay *ASG* which opens contact *ASG1* in series with contact *AOV* and closes contact *ASG2* which completes the circuit to the opening contactor *AO* of air switch *A*. This contactor is kept energized by its auxiliary contact *AO* until the air switch travels to the full open position.

When line *LA* is re-energized, contact *AUV* opens; relay *ASG* is de-energized thereby opening contact *ASG2* and closing contact *ASG1*. A circuit is completed through over-voltage relay contact *AOV* and contact *TO1* of lock-out relay *SGRA* to the closing contactor *AC* of air switch *A*. This circuit is maintained through auxiliary contact *AC* and the air switch travels to the closed position. When the air switch is moving from the open to the closed position the operating coil *TO* of lock-out relay *SGRA* is briefly energized through auxiliary switch *Aa/b* which is closed only when the air switch is in motion; contact *TO1* opens and contact *TO2* closes completing a circuit to the motor *M* of the lock-out relay. If the line remains energized for five seconds, this motor will complete its travel, close contact *M* and energize reset coil *TR* of the lock-out relay provided that the air switch is still closed. If, however, the air switch again opens before the motor completes its five second timing period, as would happen if there were a fault on the substation bus, the reset coil will not be energized; contact *TO1* will remain open, and air switch *A* will not again close automatically. It will remain open until an operator closes it. A two-pole double-throw automatic manual transfer switch is provided to transfer the control to a standard control switch. Manual mechanical operation of the air switch is possible also if need arises.

Figures 8, 9 and 10 graphically show the time schedule of service restoration for the sectionalizing station of Figure 6. Circuit breakers *C* and *D* are set to reclose at 5-second and 30-second intervals. Air switches *B* and *C* are set to trip about one second after the lines are de-energized and to close about three seconds after lines have been again energized. The shaded portion indicates the period of time, five seconds or more, that the closing circuit is rendered nonoperative after a closing operation. Figure 8 shows that after a temporary fault, the two line sections are re-energized in five seconds and

Figure 16. Service restoration schedule for temporary fault anywhere on line *HK* of Figure 15

station *N* in about nine seconds. Figure 9 shows that section *BD* is re-energized in five seconds and station *N* in nine seconds after the occurrence of a permanent fault on section *CA*. Figure 10 shows that both sections of the line are re-energized in 35 seconds after a fault on the bus of station *N*; the two open air switches *A* and *B* isolate station *N*.

Two Sectionalizing Stations With Three Power Sources

A network with three sources of power and with two automatic sectionalizing air switch stations is shown in Figure 11. Circuit breakers *A*, *F*, and *G* are set to reclose at 5-second and 30-second intervals. The four air switches, *B*, *C*, *D*, and *E* open one second after the lines are de-energized. Air switches *B*, *C*, and *E* close three seconds after their respective lines have been energized; air switch *D* closes 15 seconds after its line has been energized. Figures 12, 13, and 14 respectively show service restoration schedules for a temporary fault on the network, a permanent fault between air switches *B* and *C*, and a permanent fault between air switches *D* and *E*. The shaded portion indicates the period of time, five seconds or more, that closing circuits are rendered nonoperative after a closing operation. The closing time of fifteen seconds for air switch *D* is a requirement in order that the two good sections of line may be joined together after switching has taken place because of a permanent fault on the bus of either sta-

Figure 17. Service restoration schedule for permanent fault on section *FE* of Figure 15

tion *N* or station *P*. The time setting of air switch *D* must represent the sum of the closing time of air switch *C* plus its lock-out relay reset time plus approximately five seconds for safety factor.

Figure 12 shows that all sections of the line including stations *N* and *P* are re-energized within nine seconds after a temporary fault has occurred anywhere on the network. Airswitch *D* closes about twenty seconds after the fault occurs, and the entire network is again restored to normal operating condition.

Figure 13 reveals that with a permanent fault at station *N* between the air switches *B* and *C*, section *FE* including the bus of station *P* is re-energized in about nine seconds and all other sections

Figure 18. Service restoration schedule for permanent fault on section *CD* of Figure 15

again have power in 35 seconds; station N is isolated. Stations J and K are joined by the closing of air switch D in fifty seconds.

Figure 14 reveals that with a permanent fault at station P between air switches D and E all sections of the line including station N receive power in about 38 seconds and stations J and H are joined together; station P is isolated.

Sectionalizing Stations Connected in Series

The problem of operating two sectionalizing stations in series arises when there is not a third source of power to feed the mid-section. Figure 15 illustrates that situation with stations N and P connected in series in a line between power source stations H and K. Circuit breakers A and F are set to reclose at 5 and 30 second intervals. Air switches B, C, D, and E open about one second after their line sections are de-energized. Air switches B and E close about three seconds after their respective line sections have been energized. Air switch C closes 10 seconds after potential is restored to either section CD or to the bus of station N; air switch D closes 10 seconds after potential is restored to either section CD or to the bus of station P.

A potential transformer can be installed on the bus at stations N and P to determine their energized condition; more economically, the energized condition of station N can be detected by an electrical circuit combining the facts that the potential transformer on line AB is energized and that air switch B is closed. A similar recognition of station P bus potential can be obtained by using the potential transformer on line FE and the fact that the air switch E is closed. The control

Figure 19. Service restoration schedule for permanent fault on bus of station P of Figure 15

Figure 20. A single source line with two sectionalizing stations in series; and its service restoration schedule for a temporary fault anywhere on the line

scheme of air switches C and D requires the addition of a simple voltage transfer relay; otherwise the control scheme of the four air switches is exactly the same as that (Figure 7) of other sectionalizing stations discussed in this paper.

The service restoration schedule shown in Figure 16 covers the case of a temporary fault anywhere between stations H and K. Power is restored in about nine seconds to station AB including station N and to section FE including station P; approximately 10 seconds later power will be restored to section CD and the entire line will be restored to normal operating condition. Figure 17 shows the schedule for a permanent fault on line section FE; power is restored to section AB and station N within nine seconds; section CD is energized 10 seconds later and station P ten seconds still later. Section EF is isolated. A similar train of events will take place for a permanent fault on line section AB.

Figure 18 shows the restoration schedule for a permanent fault on section CD and reveals that power is restored to sections AB and FE in 35 seconds, and to stations N and P about three seconds later.

Figure 19 shows the restoration schedule for a permanent fault on the bus of station P. Sections AB and FE are re-energized in 35 seconds, station N in about 38 seconds, and section CD in about 48 seconds. A schedule for a fault on the bus of station N would reveal similar results.

Figure 15 shows two critical stations, N and P, in the line between power source stations H and K. Even without those critical stations, it is occasionally desirable to break a line into two or three sections so that a permanent fault on one section may be isolated and service restored to the other sections. The line diagram then becomes that of Figure 15 with the omission of stations N and P and of air switches C and D. Circuit breakers A and F and air switches B and E operate exactly as described previously in the discussion of Figure 15. Sections AB and FE are re-energized five seconds after a temporary fault and section BE is energized about three seconds later. Permanent faults on line sections are isolated promptly and service is restored to the good sections.

The line between stations H and K can be divided into two sections by a single automatic air switch so wired that it will close when both line sections are energized. A potential transformer on both sides of the air switch is required.

Sectionalizing Air Switches in a Single Source Feeder

Figure 20 illustrates a line HK with a power supply from station H only. The line is long and heavily loaded; there are valid operating reasons for sectionalizing the line into three parts upon occurrence of a fault and thereafter restoring power to as much of the line as possible. Circuit breaker A has a reclosing setting of 5 and 30 seconds. Air switch C and E both open when the line is de-energized; air switch C closes when section AC is energized and air switch E closes when section CE is energized. The air switch control scheme is exactly as has hitherto been described for the sectionalizing type (see Figure 7).

Figure 20 shows also the service restoration schedule for a temporary fault occurring anywhere on the feeder; the entire feeder is re-energized in about 18 seconds. With a permanent fault on section EK the other two sections will be re-energized in about 38 seconds. With a permanent fault on section CE

power will be restored to section AC in 35 seconds.

Conclusions

The types of automatic air break switch application described in detail in this paper together with other types of which brief mention is made can all be effectively used to mitigate the problem of service restoration. The automatic air switch not only isolates faulted equipment, preventing further damage, but also isolates faulted line sections, permitting other sections to be re-energized. By their automatic action they designate within definite limits the location of faults and thus assist in the task of directing repair crews to the affected area. Combinations of sectionalizing and transfer types on the 25-kv network of the West Penn Power Company have been very successful.

Because of their satisfactory performance over a period of many years, West Penn Power Company is continuing to make automatic air switch installations where unusual or critical loads exist, some of which might otherwise require the installation of oil circuit breakers. Automatic air break switches have their limitations of application because of their slow speed of operation and because of their inability to reliably open currents of fault magnitude; they cannot take the place of circuit breakers when those operating characteristics are essential.

For service restoration purpose the automatic air switch is an outstanding device accessory to and complementary to the oil circuit breaker.

Discussion

R. S. Smithley (Duquesne Light Company, Pittsburgh, Pa.): This paper shows what can be done toward improving service to loads served at transmission voltages, that do not justify automatic service. The schemes developed and used by Reardon restore service in a very short time. Because of the desire for restoration of service in a short time (approximately 10 seconds), the schemes require the use of high tension potential or station service transformers on each line, fast operation of air break switches and possible closing of air break switches against faults. The frequent operation of air break switches and the closing of these switches against faults apparently does not result in need for excessive maintenance of the switches.

The Duquesne Light Company has 24 service-restoring installations for nonautomatic stations on the 23-kv system. Several more installations will be made in connection with unit substations. The outstanding differences between the general scheme employed by the Duquesne Light Company and that employed by Reardon are basically five.

1. Use of 3-phase bus potentials instead of single-phase line potentials.

The 3-phase bus potentials generally are obtained from low-tension bus potential transformers.

2. Attempt to re-energize the line before sectionalizing.

Avoids necessity of operating air-break switches on temporary faults.

3. Timing is done at no-voltage and a battery source is used for operating the air-break switches.

Operating the switches while the station is dead necessitates a battery because there are no high tension line potential transformers.

4. No provision is made for bus faults at the sectionalizing station.

May cause outages to other nonautomatic customers on the line.

5. Longer time may be required to restore service.

The economic advantage of using existing potential transformers instead of high tension potential transformers on each line results in a lower cost installation, at the expense of increased service restoration times which may be of the order of one minute. The performance of these schemes has been entirely satisfactory.

Edward W. Kimbark (Northwestern University, Evanston, Ill.): The service-restoration schemes described in the paper entail 8-second interruptions of service to tapped loads upon the occurrence even of temporary faults. These interruptions could be made much shorter by providing the circuit breakers at one or more points of feed with high-speed initial reclosure. If this were done, service would be restored in one-third to one-half second after occurrence of a temporary fault and with no operation of the air-break switches. Permanent faults could be isolated selectively in accordance with the schedules described in the paper when the high-speed reclosure did not succeed.

The addition of high-speed reclosure as just suggested would, of course, necessitate larger circuit breakers because of the more severe duty cycle and also, on lines fed from two or more points, would require some form of pilot relaying. The additional cost of circuit breakers and relays might be warranted on some lines supplying power to important loads, especially on lines so constructed that the majority of faults are temporary.

Kenneth N. Reardon: The discussions from the floor following the presentation of my paper and the many conversations in which I subsequently took part definitely indicate that a great interest exists among operating engineers in the use of the automatic air switch as a service restoring device. The field of application is apparently widespread geographically; satisfaction with results obtained and active plans for continued application characterized the comments. O. L. Giersh of the Duke Power Company revealed in his remarks during the meeting that the automatic air switch by performance has earned for itself an important position in his relaying and service restoration program. Several hundred are automatically controlled so as to act as back-up devices for relayed circuits; mention was made of their use in place of fuses for the protection of transformer banks. More information, as might be given in an "experience paper," would be of interest.

Edward W. Kimbark, professor of Northwestern University, pointed out the possibility of reducing the duration of interruptions to an even greater extent than described in my paper by the expedient of using an initial high-speed reclosure of circuit breakers at one or more points of feed. Recognition was given by him to the fact that a prerequisite for the success of such immediate reclosing might in many cases be the installation of pilot wire relaying. True, instantaneous reclosing could reduce the duration of interruption in the case of a temporary fault to the attainable minimum of time. It is a practice most applicable, in our opinion, when the automatic air switch installation is of the transfer type and in many instances is used on the West Penn Power Company lines. Mention to that effect was not made in my paper which was written to present the general picture and the various types of application. Specific installations with their requirements for pertinent timing sequences were left to the ingenuity of the individual engineer.

Instantaneous reclosing of circuit breakers is less feasible at the two or three ends of lines of which the sectionalizing type of air switch is a part, but again may well be considered for a specific installation. In our case, the opening of circuit breakers on such lines is not simultaneous at all points, but is more or less sequential. Our experience has shown that it is better to automatically sectionalize the line and then with surety re-energize it section-by-section thereby giving definite possibility of restoring service to the bus between the automatic sectionalizing switches. Pilot relaying is not applicable in our case because numerous transformer banks with fuse protection and customers with loads of considerable magnitude are connected between the source substations. Unbalanced load currents would flow in pilot circuits under normal conditions were they to be installed and lines might be tripped unnecessarily when faults in connected transformer banks call for the blowing of fuses.

R. S. Smithley of the Duquesne Light Company presented interesting data on the use of automatic air switches by the Duquesne Light Company and described various important operating functions which have been achieved.

G. E. Heberlein of the Railway and Industrial Engineering Company commented upon the use of automatic air switches in general and asked for an expression of our experience of connecting potential and power transformers directly to the lines without fuses. We have had excellent operating

experience in that respect and do not consider fuses to be necessary. In answer to his question, we stated also that counters are used on the air switch mechanisms some of which operate mechanically, the majority electrically. No effort is made to transmit information to a dispatching location that the air switch has operated or that the air switch is in a contrary-to-normal position. The use of current transformers or potential transformers, wherewith to obtain directional relaying, was discussed in response to Heberlein's question and we pointed out that we have strived to obtain automatic air switch operation without resource to the complications of directional selectivity, and have accomplished that end very successfully.

L. F. Ferri of the Ohio Public Service Company presented an interesting discussion of automatic air switches with timing co-ordinated with reclosing circuit breakers and repeater fuses. His discussion was informative and indeed appreciated.

I suggest that the subject of automatic air switches is one that can well bear further discussion by AIEE groups in the various geographical locations and that an exchange of ideas and operating practices will be profitable.

Relaying Difficulties Disclosed by Staged-Fault Tests

W. A. MORGAN
MEMBER AIEE

BYRON EVANS
MEMBER AIEE

HIGH-VOLTAGE staged-fault tests previously have been described before the AIEE.[1] However, unusual data and experience obtained from staged-fault tests by the Bureau of Reclamation, Denver, Colo., on a power system in Arizona may be of help to engineers confronted with similar problems. Some of the difficulties encountered indicate the need for reviewing the design of some presently accepted types of modern equipment. The occasion for the tests was the installation of long-line-type directional-distance-carrier relaying and 20-cycle reclosing circuit breakers on the two 161-kv 140-mile Parker–Phoenix transmission lines.

As a result of the tests and corrective measures taken, the system operated through the 1947 summer lightning season with correct carrier-current relay and 20-cycle reclosing circuit-breaker operations for the two lightning flashovers that occurred. However, oscillographic records were necessary to reveal the unforeseen difficulties. If the protective equipment on the two 161-kv lines had been put into service without these tests, it is probable that the first natural line fault would have caused a severe interruption to service, and data necessary to determine the cause of the interruption would not have been available. Two series of staged-fault tests were made. The first tests of February 1–2, 1947, disclosed a number of relay troubles. The second tests of February 15–16, 1947, were made after these troubles had been either corrected or remedied by temporary expedients.

Paper 48-12, recommended by the AIEE carrier current and relay committees and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted November 5, 1947; made available for printing December 8, 1947.

W. A. MORGAN is group head of, and BYRON EVANS is an engineer in, the power system technical group of the branch of design and construction, Bureau of Reclamation, Denver, Colo.

The authors wish to acknowledge the co-operation received from engineers of the Southern California Edison Company, Metropolitan Water District of Southern California, Central Arizona Light and Power Company, Salt River Valley Water Users Association, Tucson Gas Electric Light and Power Company, Imperial Irrigation District, United States Indian Service, and other interconnected utilities.

Description of the Power System

The location of the two Parker–Phoenix 161-kv lines with respect to the interconnected system that existed at the time of the tests is shown in Figure 1. The Parker power plant was placed in operation in December, 1942. Its output was soon absorbed by the Phoenix, Yuma, Coolidge, and Tucson loads, and the initial, single 161-kv Parker–Phoenix line proved to be inadequate. The second 161-kv Parker–Phoenix line was put into service during 1946. Both 161-kv Parker–Phoenix lines have overhead ground-wires. The critical need for power in the central Arizona area has required a larger capacity 230/161-kv interconnection at Parker power plant to make more power available from Hoover power plant. Davis power plant, now under construction, will connect into this power system and augment the present available power supply by 225,000 kw. The importance of the relay and 20-cycle reclosing circuit-breaker performance on this rapidly growing power system is appreciated.

Calculating Board Stability Studies

Calculating board studies were made in July 1944, after it was apparent that the single 161-kv Parker–Phoenix transmission line was inadequate. Stability studies and system impedance measurements demonstrated the need for carrier-current relaying and 20-cycle reclosing circuit breakers, and determined the relay characteristics required to prevent false relay operation on the low impedances which accompany power swings. Figure 2*B* illustrates one of the power-swing studies and shows that a load of 103 megawatts, which is in excess of the capacity of one 161-kv Parker–Phoenix line, may be delivered to Phoenix, and stability will be maintained when a fault occurs on the other line, provided 20-cycle reclosing circuit breakers are used. In Figure 2*B* it will be noted that the relative angles of the machine internal voltages with respect to the Parker machines as a reference are plotted since the criterion of stability is determined by the swing of the machines with respect to each other. This method of representation is believed to be more direct and easier to interpret than the usual method of plotting the actual angular change of all the machines. Figure 2*C* shows how the impedance at the Parker Terminal, corresponding to the power swing on the unfaulted line, is reduced to values which would cause undesirable tripping of the unfaulted line if conventional distance relays were used. The 0.35 second point *P* of Figure 2*C* has

Table I. Staged Fault Tests

Performed on Parker-Phoenix Two 161-Kv, 140-Mile Transmission Lines

Test No.	Type of Fault	Fault Location
Initial tests, February 1–2, 1947

8	Line-to-line	Line 2 at Parker
9	Double line-to-ground	Line 2 at Phoenix
10	Double line-to-ground	Line 2 at Parker

Figure 1. Single-line diagram of system

been plotted on Figure 3 to show that undesirable relay operation is prevented by the relays now installed on these lines.

The Parker–Phoenix system would become unstable if the circuit breakers on the faulted line were not reclosed at about 0.35 second. This is indicated by Figure 2*B* which shows the relative angles of the machines increasing rapidly before 0.35 second. The dashed line plotted on Figure 2*C* shows that the impedance seen by line number 2 relays, without rapid reclosure of line number 1 circuit breakers, would be within the tripping zone of the special relays now in service. This is satisfactory since the system would be unstable without rapid reclosing, and it would be desirable to separate by tripping the remaining 161-kv line.

Long-Line-Type Directional-Distance-Carrier Relaying and 20-Cycle Reclosing Circuit Breakers

The characteristics of the phase relays with the settings used at the Parker end are shown in Figure 3. Calculating board studies indicated that a restricted impedance area characteristic was required to prevent tripping during power system swings. These relay impedance requirements were met by using long-line-type directional-distance relays for fault detection, and blinder relays for preventing tripping on some of the power swing impedances. The carrier-current ground relays were the instantaneous directional-type with one element for initiating carrier-current tripping and another more sensitive element for initiating carrier-current blocking for faults external to the protected line. The ground backup protection is provided by directionally-controlled, time-over-current relays.

The 20-cycle reclosing circuit breakers had been installed on line 2 only, at the time of the staged fault tests. These circuit breakers are rated 5 cycles interrupting time and each pole has a resistor of about 1,300-ohms connected across each of the two interrupter main contacts. The operating mechanisms are the pneumatic-type. The 20-cycle reclosing circuit breakers for line 1 had not been received at the time of these tests and the existing oil circuit breakers were used. These circuit breakers are rated 5 cycles interrupting time, with a mechanical-type operating mechanism which cannot be adapted to 20-cycle reclosing service. There are no resistors across the main contacts of these circuit breakers.

Method of Applying Faults

The method of applying the 161-kv faults is illustrated by Figure 4. This method has been described in detail in a previous article.[1] It is sufficient to say that no difficulty was experienced with this method during the Parker–Phoenix tests. The arrangement of weights and pulleys provided a fast, convenient method for renewing the iron wire after each test. Oscillograph connection changes between tests required more time than did the renewal of the iron wire. Iron wire was preferred to ordinary fuse wire because it has sufficient tensile strength to withstand the loads imposed by the fault-applying apparatus. Also, the fault arcs caused by the fusing of fine iron wire result in less vaporized metal and have high-resistance characteristics similar to arcs caused by lightning flashovers. The faults were actually applied to the transfer busses which were connected to appear electrically as part of the line.

Description of Tests

The tests were scheduled during the light-load period over week ends when the load demand could be reduced to about 40 megawatts. With this power transfer, it was hoped to reduce the possibility of an interruption to service at Phoenix in case the 20-cycle reclosing circuit breakers failed to reclose, since it was thought that the unfaulted line could carry this load despite the power swing which would result with the fault. The schedule of the tests is shown in Table I.

During the tests a 12-element oscillograph was operated at Phoenix substation, a 9-element oscillograph was operated at Parker power plant, and a 7-element oscillograph was operated at Gene pumping plant. Oscillograms for the Gene oscillograph are not illustrated; however, these Gene oscillograms revealed that the slow relay operations in the February 1–2 tests caused power swings between Hoover and Parker of up to 40 megawatts, while these power swings during the February 15–16 tests, with faster relaying times, were only about half as great. Also, an instantaneous-type ground relay at Gene pumping plant operated during one of the ground faults on the 161-kv Parker–Phoenix line 1 at Parker because of the prolonged restriking time of the older-

type circuit breakers on that line. Similar faults on line 2 with the modern circuit breakers did not cause ground-relay action at Gene pumping plant. The oscillograms from the Parker and Phoenix oscillographs were of inestimable value in overcoming some of the difficulties, the principal ones of which are described in the following paragraphs.

False Operation of Carrier-Current Ground-Relay Elements on Line-Charging Transient Currents

Residual-transient current in the current transformers of the lines and of the transformer-bank neutrals when the 161-kv lines were energized by closing the line oil circuit-breakers is shown in Figure 5. The frequency of the transient current for these 161-kv lines is about 240 cycles. Although the duration of this transient is short, the magnitude is sufficient to operate the carrier-current ground-trip *GD2* elements when the relays are given the low settings required on this installation. It is believed that the frequency of this transient corresponds to the resonant frequency of the line capacitance and transformer bank reactance. The magnitude depends on the time of the cycle that the circuit-breaker main contacts close to energize the line. This same phenomenon has occurred on the 230-kv lines at Grand Coulee power plant even though the three poles of the circuit breaker had been carefully adjusted to assure the simultaneous mechanical closure of the main contacts of all three phases. It is believed that the line phases are energized at different instants due to the breaker-main contacts being bridged by arcs before they close mechanically.

The 161-kv lines were energized a number of times from the Parker end and it was found that the *GD2* relay on line 1 would operate occasionally with a setting of 1.4 amperes, whereas the ground relay on line 2 was less vulnerable. The settings of the *GD2* relays were left at 1.5 amperes for line 1 and 1.4 amperes for line 2. It is desirable to set the relays at 0.7 ampere to assure fast positive operation for faults during minimum system operating conditions. False tripping by these relays could be prevented by the use

Table II. Reclosing Time Required to Prevent Re-establishment of Fault Arc

Test	Type of Fault	Time Interval Circuit Breaker Main Contacts Were Open	Was Fault Arc Re-established When Circuit Breaker Reclosed?
No. 2, Feb. 1–2	Phase-to-ground	8.4	No
No. 5, Feb. 1–2	3-phase	8.2	Yes. The fault restruck between *B* and *C* phases
No. 7, Feb. 15–16	Phase-to-phase	11.2	No

of a time-delay relay, but this is considered undesirable. A high-frequency filter improvised from capacitors and reactance coils available at the project was used to by-pass this line-charging transient-current from the relay-operating coil. Tests with this improvised filter circuit demonstrated some benefit and indicated that a correctly designed filter would prevent false operation of these relays, and the manufacturer has been requested to design and build filters for this installation.

The line-charging tests indicated that the interrupter-unit resistors used in the line 2 oil circuit breakers are somewhat effective in reducing the magnitude of the line-charging residual transient-current, because this current was larger on line 1 where the circuit breakers are not equipped with these resistors. This is illustrated by Figure 5. However, Figure 8 illustrates that the interrupter resistors in the circuit breakers do not obviate the need for filters in the carrier-ground relay circuits to prevent their false operation in low settings.

Contact Bounce of Carrier-Ground Relay Element

The carrier-ground relay element *GD1* starts carrier when its normally closed contact opens. Tests 1 and 2 of the February 1–2 tests demonstrated that this contact would intermittently start carrier and cause the carrier alarm bell to ring in the control room, immediately following the clearing of a line fault which had produced relay torque to hold this contact in the normally closed position. This is shown in Figure 6 where the complete oscillograph trace for line 1 carrier signal shows that carrier is periodically started and stopped about 13 times over a period of 51 cycles. This bouncing or vibration could not be duplicated in the laboratory, but since it had occurred elsewhere before, it was thought to be caused by the sudden reduction in contact pressure under certain current conditions resulting when the relay torque produced by the current element goes to zero when the fault is cleared. The ratio of operating and restraining-coil currents may be a factor, but this was not investigated in the laboratory. The relay contacts are of the new non-bounce design which is quite effective for preventing bounce when the contacts "make" under relay torque. To correct the bounce of the normally closed contacts when closing torque is reduced to zero, the stationary contact assembly was modified by removing the metal disk located directly back of the stationary contact, and by putting a spacer behind the ball to hold it directly against the stationary contact so this contact is allowed only about 1/64-inch movement.

The effectiveness of this modifica-

Figure 4. Method of initiating 161-kv line faults

tion is demonstrated by comparing the oscillograph trace for line 1 carrier signal in Figure 6 with Figures 8 and 11.

Incorrect Current Transformer Connections

The polarity of the connections of the directional-ground relay-polarizing current transformers in the main transformer bank neutrals at Parker power plant was assumed to be correct prior to the February 1–2 staged fault tests. The plant had been in operation about four years and the single 161-kv Parker–Phoenix line had relayed correctly so far as was known; however, the February 1–2 staged fault tests revealed that the polarizing current was nearly zero. See oscillograph trace, *In*, of Figure 6. A thorough check revealed that two of the four 161-kv neutral-current transformers were connected for reverse polarity, and if it were not for the difference in impedances of two-winding and three-winding transformer banks, and the small polarizing current supplied by the 69-kv neutral-current transformers, there should have been zero polarizing current. The explanation for this wrong connection probably is that Parker power plant was completed during the war when there was an urgent need for electric power and a shortage of manpower, and the connection of the two current transformers was left to an electrician to connect the same as the first ones had been connected. This had not been detected previously since the induction-type, directionally-controlled, ground relays had functioned several times before. The long operating time had not been measured previously with an oscillograph. This incorrect connection of the neutral-current transformers was responsible for the only interruption to service at Phoenix during either the February 1–2, or the February 15–16 tests. The fourth test of the first series caused tripping of both 161-kv lines in a slow time by the backup ground relays and reclosing of the one line was unsuccessful.

Incorrect Carrier Control Circuit

The staged-fault tests revealed a defect in the carrier-control relay circuit which was not apparent in checking through the drawings or circuits prior to the staged fault tests. With the incorrect circuit, carrier-blocking was allowed to start on the faulted line at the nearest terminal as soon as the oil circuit-breaker tripping relay was energized. This blocked tripping at the opposite end of the line until the circuit breaker at the faulted terminal had opened. This required that the relays at the far terminal had to operate before the auxiliary tripping relay of the circuit breaker at the faulted terminal was energized, otherwise sequential tripping would result. The circuit was corrected by relocating a circuit-breaker auxiliary, *a*, switch contact which was already in use in the relay-control circuit. This change did not require any new circuit wiring. The incorrect starting of carrier-blocking may be seen in Figures 6 and 7 of the February 1–2 tests. Correct carrier-control is shown by Figures 8 and 11.

The pips that occur in the carrier-current traces for line 2 in Figures 8 and 11 are not due to incorrect carrier-relay action or contact bouncing. This fact was established during one of the tests by connecting a jumper around all the relay contacts that would start carrier when their contacts were opened. This test showed that the pips in the carrier-current trace occurred as before, at the time of the fault, clearing of the fault, and at reclosing.

Figure 5. Residual-transient currents produced when 161-kv circuit-breakers were closed to energize the lines

(*a*) Maximum transient recorded on line 1; (*b*) maximum transient recorded on line 2

The pips that occurred in the carrier trace, therefore, are probably due to extraneous frequencies which accompanied the line disturbances and were within the range of the carrier-frequency channel.

Figure 6. Oscillogram from Parker oscillograph for test 2, February 1–2, 1947. Phase A-to-ground fault on line 2 at Phoenix

Note evidence of contact bounce of carrier-ground *GD-1* relay, small ground-relay polarizing current, and incorrect carrier-blocking signal on line 2

Inadequate Backup Protection with the Long-Line-Type Directional-Distance Carrier Relay Scheme

In the conventional long-line-type directional-distance carrier relaying scheme, the third element *M3* is set for fast operation in the direction to start carrier-blocking, which is the opposite direction for which the first and second elements *M1* and *M2* are set to operate.[3] At a given terminal, *M3* does not provide

Figure 7. Oscillogram from Phoenix oscillograph for test 5, February 1–2, 1947. Three-phase fault on line 2 at Parker

Note slow operation of Phoenix phase relays, incorrect carrier-blocking signal on line 2, restriking of fault arc, and failure of Phoenix phase relays to operate on phase-to-phase fault

backup protection for *M2* with this arrangement as would be the case if all three elements were set to protect in the same direction, which is the practice where carrier-blocking is not used. The need for backup protection for the second element was proved during one of the February 1–2 tests. A line-to-line fault at Parker power plant was not cleared by the Phoenix phase relays. This fault was finally cleared when it developed into a 3-phase fault and caused the Phoenix phase relays for the other two phases to operate. Figure 7 shows the oscillogram for this test. The oscillogram indicates that simultaneous clearing of the staged 3-phase fault was not obtained and the 20-cycle reclosing of the first circuit breaker

to open re-established a line-to-line fault, phases *B-C*, as sufficient time had not elapsed for the deionized fault arc gasses to disperse. Figure 9 shows how, after about 90 cycles, the fault arc traveled upward and fortunately contacted the third phase in the transfer bus above, which finally caused the phase *A-B* and phase *C-A* relays at Phoenix to operate. Later, before the February 15–16 tests, it was found that the blinder relay for phase *B-C* on line 2 was binding and operated erratically on small currents. All the relays were checked over for operation on load current, and it was found that in some cases erratic operation was also caused by the sticky film that was found on all parts within the case and this film was removed with alcohol. This sticky film apparently was thrown off as a vapor from the insulation varnish on the potential coils during the short period of a few weeks that the relays had been energized prior to the staged fault tests. A cause of slow operation was the small fault current of 3.2-amperes in the relays. Operating time tests with currents of about three amperes were made on the directional distance and blinder relays, and the impedance reach of some of the relays was increased to speed up the relaying times.

Figure 8. Oscillogram from Phoenix oscillograph for test 6, February 15–16, 1947

Phase *A*-to-ground fault on line 2 at Parker. The fault arc was maintained through the oil-circuit-breaker interrupter resistors after the main contacts opened. Note the 240-cycle transient currents when Phoenix oil-circuit-breaker main contacts reclosed to energize the 161-kv line

It is planned to increase the current in the long-line directional-distance relays by auxiliary-current transformers because of the small-fault currents available under certain conditions. The manufacturer has worked out a circuit arrangement involving the addition of another offset *M2*-type unit which will provide the desired backup protection for the *M2* element and will also simplify and speed up the tripping circuit for faults which require both *M2* and blinder-relay action.

It is believed that the present practice of reversing the direction of the third element when the special long-line directional-distance relays are used with carrier current should be reviewed because of its weakness from the standpoint of backup protection for the second element. An alternate relaying scheme, with emphasis on simplicity, would be to use the phase-comparison-, or *HKB*-type of carrier-current relaying which would protect for all but 3-phase faults in most cases, and to use the special long-line directional-distance relays for backup with all three elements set for the same direction. The 20-cycle reclosing circuit breakers would reclose whenever faults were cleared by the carrier-current relays, which would be for all faults except the 2 or 3 per cent of the faults which are 3-phase and which are probably most likely to be of a permanent nature when reclosing is not desirable.

Ultra High-Speed Reclosing Time as Effected by Low-Ohmic Resistors Paralleling Main Circuit-Breaker Contacts

The application of ultra high-speed reclosing circuit breakers to systems with higher voltages or for reclosing times faster than 20-cycles, may be reason for further study to determine the optimum value of resistance which should be used for the main-contact interrupter resistors of some modern oil circuit-breakers. The interrupter resistors in the 20-cycle reclosing circuit breakers used on line 2 are especially effective in preventing or

minimizing arc restrikes when interrupting line-charging current. However, the oscillogram in Figure 8, and others, show that the fault arc was maintained for an additional two or three cycles after the main contacts opened, although the fault current was reduced by the interrupter resistors. This encroaches on the time allowed for the deionized fault gasses to disperse from the faulted line between the time the main circuit breaker contacts open and before they reclose. It also brings up the question of whether the circuit breakers are 5-cycle circuit breakers, or 7- or 8-cycle, depending upon whether the time is taken as when the main contacts open or when the fault is actually cleared. It would appear that the oil circuit-breaker standards committee would be interested in this problem.

Figure 9. Fault arc, test 5, February 1–2, 1947

Initial fault was on all three phases of line 2 at Parker. See Figure 7 oscillogram for nature and duration of faults. Maximum fault arc current about 2,100 rms amperes

Time for Ionized Arc Gases to Move Upward or Disperse

Data as to the time it takes an arc to travel upward with little wind assistance may be obtained from Figures 7 and 9. Figure 9 shows the initial 3-phase fault which was applied to the jack bus and shows how the line-to-line fault arc, which occurred on reclosing, traveled upward until it contacted the third phase in the transfer bus above. The distance from the jack bus to the transfer bus above is 17 feet, and the time on the oscillograph was about 119 cycles. This information may be of interest in connection with vertical-configuration transmission lines.

Figure 10 shows the difference in photographed intensity due to the two line-to-ground faults being applied to the two phases at different times. The relative amounts of arc gases and deionized air probably correspond to the photographed arc sizes.

Table II provides data to illustrate the shortest time it may be feasible to allow as a de-energized time for reclosing-line circuit breakers. The spacing between phases in the jack bus is 12 feet compared with 17 feet between conductors on the 161-kv Parker–Phoenix transmission line. The times given in the table are for the intervals between the opening and reclosing of the main contacts. Since the circuit is energized through the interrupter resistors in the circuit breaker during part of this interval it would appear that these times should be reduced by two or three cycles to represent time fault is cleared, and possibly by four to six cycles, to correspond to actual de-energized circuit time.

Satisfactory Relay and Circuit-Breaker Operation

Figure 10. Fault arc, test 10, February 15–16, 1947

Double line-to-ground fault on line 2 at Parker. Maximum fault arc current about 2,600 rms amperes. The phase *A* fault arc was brighter due to longer duration. See Figure 11 oscillogram for detail on fault duration

Figure 11. Oscillograms from test 10, February 15–16, 1947

Double line-to-ground fault on line 2 at Parker

preliminary modifications discussed previously had been made are shown in Figure 11. Correct relaying and carrier blocking occurred by action of the ground relays and the faulted line was cleared almost simultaneously at both ends. The reclosing circuit breakers energized the line from both terminals within about 1.6 cycles of each other.

The oscillograms from the February 1–2 tests made it possible to make the remedial measures under which the relays are now operating. After the permanent changes are made it is expected that the relaying will be faster for all types of faults and more reliable for possible minimum system conditions.

No Discussion

X-Ray Thickness Gauge for Cold-Rolled Strip Steel

W. N. LUNDAHL
ASSOCIATE AIEE

THE EVOLUTION of new and higher speed processes, new materials, and the trend toward greater precision and quality have necessitated development of more satisfactory gauging methods.

Most gauges now in use are of some electromechanical contact type. Many limitations arise due to the necessary maintenance of direct contact between the gauging head and the test material. Metals with finished surfaces tend to be scratched or marred at the contact point. Soft materials such as some plastics and paper would be torn by a contact type gauge. High temperature materials such as plate glass as it comes from the lehr (annealing furnace) are impossible to gauge continuously. Until recently, no satisfactory continuous gauging device had been developed for the steel industry's hot mill. The tremendous speeds and the high temperatures at which the modern mill operates have defied previously known gauging methods. Increasingly high speeds of cold mill operation also have increased the necessity of a noncontact gauge.

The combination of X ray and electronics lends itself admirably to many gauging problems. The outstanding advantage of this combination is that there is no physical contact between the gauge and the gauged material. Since it cannot scratch, there is little discrepancy due to paint and lacquer coatings; it is not subject to progressive shift in calibration due to mechanical wear or through accumulation of scale or oxides picked up from the material. It enables continuous gauging of soft or thin material, and limitations due to temperature theoretically do not exist. Satisfactory continuous high-speed gauging becomes practical since vibration and centrifugal force are not factors.

Paper 48-14, recommended by the joint subcommittee on electronic instruments, industrial control committee, and the mining and metal industry committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted November 5, 1947; made available for printing December 18, 1947.

W. N. LUNDAHL is design engineer with the Westinghouse Electric Corporation, Baltimore, Md.

Theory

Basically, X-ray gauging is accomplished by irradiating the material under test and in effect, measuring the drop in radiation intensity through that material. The form of the standard general absorption equation is

$$I = I_0 e^{-\mu \rho t} \tag{1}$$

where I_0 is the original intensity, I the transmitted intensity after filtration, μ the mass absorption coefficient, ρ the density of the material, and t the thickness of the material. The absorption coefficient is a function of the atomic number of the absorbing matter and the wave length of the radiation. It is independent of physical state, state of aggregation and temperature. This equation is theoretically applicable only to monochromatic X rays.

The heart of the X-ray thickness gauge is the pickup device which measures I quantitatively. Certain physical and chemical effects may be utilized as quantitative measurement of X-ray intensity. Four of these effects may be used with various degrees of practicability and success. These phenomena which result in various irradiated substances are

1. Heat content increase.
2. Photographic film exposure.
3. Gas ionization.
4. Fluorescence.

The first effect, which occurs where a material absorbs a large percentage of the primary radiation, appears as a measurable net increase in the heat content of that material. The second effect, commonly used radiographically, results from X radiation reducing silver bromide to silver in a photographic emulsion. The third effect is obtained when a gas, irradiated by X rays, becomes ionized to a degree proportional to the energy of the incident radiation. The fourth effect results in the excitation of luminescence in some types of irradiated substances.

For industrial applications of high-speed gauging it is obvious that the first two types of mensuration are not practical. Both the phenomenon of fluorescence and that of ionization, however, are quite satisfactory for high-speed application.

With the ionization principle, intensity is determined by measuring the flow of ionization current in an enclosed chamber. Utilizing the phenomenon of fluorescence the radiation is allowed to impinge upon a fluorescent material, and the resultant visible light emission is picked up by some highly sensitive photoelectric cell. The output of this cell is then proportional to the intensity of incident radiation upon the fluorescent screen.

Figure 1. A one-source one-pickup system

Figure 2. A one-source two-pickup system

The Ionization Chamber

Until recently, quantitative electrical X-ray detection and measurement were accomplished only with some form of the ionization chamber. This is mainly because the definition of the roentgen unit, used widely in radiology, is dependent upon the ionization of air. Basically, an ionization chamber consists of a metal tube a few inches in diameter and from two or three inches up to three feet or more in length. At one end is a window, consisting of a hole covered with a thin sheet of some material fairly transparent to X rays such as aluminum foil, mica, a plastic of some sort or beryllium. A metal electrode is mounted parallel to the axis of this cylinder but displaced from its concentric position to such a degree that X rays entering the window parallel to the main axis do not impinge upon the electrodes. This electrode is supported and insulated from the cylindrical chamber. With an external source of potential, the central electrode is made positive with respect to the cylindrical housing. In series with this potential source is a high value of resistance over which a potential drop indicates the magnitude of the ionization current.

It is essential that the potential be high enough to produce a saturation current so that all ions produced may be drawn across to the electrodes. The physical dimensions of this chamber, the gas used in the chamber, and the potential difference maintained between the two elements are dependent upon each other and upon the quantity and quality of the X rays being measured.

Although it is possible to ionize any gas with X radiation, the most effective gases for use in ionization chambers are those which contain a heavy atom. These produce large and easily measured ionization currents. As the X-ray beam strikes the gas in the chamber, high-speed photoelectrons are liberated. These photoelectrons have too much kinetic energy to be immediately absorbed by the gas molecules near it, and thus they break down the molecules in which they come in contact into ion pairs. There is a definite amount of energy necessary for the production of one pair of ions in a given gas. In air, for example, at the formation of each ion pair, 33 electron volts of energy are removed from the photoelectron, thus they dissipate their original kinetic energy until the electron is absorbed by a gas molecule to form a negative ion or to cause neutralization by absorption with a positive ion. When the metallic rod carries a positive charge with respect to the cylindrical chamber, the electrons will be collected by the positive rod, and the positive ions will move toward the chamber wall. This migration of ions, of course, constitutes the ionization current. The well-known Geiger-Mueller counter is a refined variation of the ionization chamber.

The Photomultiplier

Since its introduction by Hodges and Morgan[1] in 1941, the photomultiplier X-ray detector has been widely used in automatic exposure timing for mass medical radiography. This application is of the high intensity type due to the comparatively large quantity of light available. The photomultiplier has appeared to be rugged, simple, and fast but of questionable dependability for applications of high precision.

It may be well to describe the construction and operation of the photomultiplier. The photomultiplier is a high vacuum phototube whose enevelope contains not only the photosensitive cathode and the pickup anode but a number of additional elements called dynodes. Tremendous amplification is obtained by the utilization of the secondary emission principle. Each dynode is maintained at a progressively higher potential with respect to the photocathode. When a photoelectron is emitted from the photocathode, it is swept by the potential difference between the cathode and the first dynode where upon impingement upon this first dynode four or five electrons are splashed out by secondary emission. These secondary electrons are in turn accelerated to the next dynode where each splashes out four or five more electrons.

The most common of these photomultiplier types is the *RCA 931-A*. In this particular tube, there are nine dynodes; therefore, with the foregoing description of one electron splashing out four or five by secondary emission on the first dynode enables a theoretical total amplification in the order of 10^6. To give one the idea of the comparative sensitivity of this photomultiplier, the RCA Tube Handbook, volume 5-6, gives a sensitivity at 4,200 angstroms and 100 volts per dynode of 8,200 microamps per microwatt, or a luminous sensitivity of ten amperes per lumen. In contrast, the *929 type* of high vacuum phototube, which contains just the two elements, the photocathode and the anode, has a sensitivity at 4,200 angstroms of 0.037 microampere per microwatt, or a luminous sensitivity of 45 microamperes per lumen.

To convert this photomultiplier to a simple radiation pickup device, the envelope of the tube is surrounded with a sheet of X-ray fluorescent screen, and in turn is covered by black paper or other covering to keep out extraneous light.

A fluorescent material absorbs photons of high energy such as X-radiation or ultraviolet rays. These high energy photons, which are absorbed by the fluorescent material, impart a portion of their energy in the form of lower energy photons that constitute visible light. Fluorescent materials may also emit visible light under the action of high energy particles of cathode rays, alpha and beta rays. The chemistry of fluorescence is lengthy and involved. The characteristics of the screen such as basic visible light wavelength and intensity depend upon the composition of the chemicals in the fluorescent material. At this point, it may suffice to say a fast screen is needed; that is, one with a high intensity but with very little afterglow. Also, the wavelength of the visible light should be near that wavelength to which the phototube is most sensitive. A Patterson type *B* zinc-cadmium sulfide screen which represents a compromise in the necessary characteristics is commonly used.

Basic Geometrical Arrangements

It may be well at this time to discuss the various physical arrangements of the components utilized in the gauging process. Basically, all that need be involved is a single source of X radiation and an ionization chamber or photoelectric pickup placed in such a position that it may receive the transmitted radiation emerging from the test material. Practically, however, this method allows cumulative errors to destroy any semblance of dependability and precision.

Figure 3 (left). A two-source one-pickup system

Figure 4. Ionization chamber input circuit used experimentally with a one-source two-pickup system

Characteristic drifts in amplifier circuits and other allied apparatus, X-ray intensity changes due to voltage and current changes in the X-ray tube, and thermal effects all contribute toward large errors. Thus, it becomes necessary to utilize some comparison scheme where the signal obtained from the test piece may be compared to some standard signal, the complete unit having common parameters.

There are three primary methods of physical arrangement that enable greater accuracy by the progressive cancellation of cumulative errors. The first method is shown in Figure 1. This particular type utilizes one X-ray tube with two parts, two fluorescent screens mounted so as to receive the transmitted radiation from the test and master strips and an optical system for transmission of the visible light from the fluorescent material to a rotating shutter disk, which allows light resultant from a master sheet and a test sheet screen respectively, to impinge upon the photocell's sensitive surface. The shutter disk is rotated at a high-speed, and its openings alternately expose the phototube to light emitted from the test sheet fluorescent screen and from the master sheet fluorescent screen. The signal from the phototube amplifier is applied to some type of algebraic rectifier where the polarized d-c response is obtained for operation of a thickness indicating instrument, roll pressure adjustor or reject mechanism. A commutator mounted solidly on the rotating shutter disk provides phasing information for the algebraic rectifier. This system is objectionable because of the somewhat complicated mechanical arrangement and dependence upon synchronism between the electrical and mechanical components.

The second method involves the use of two pickup devices and one X-ray source as shown in Figure 2. This geometrical scheme may utilize either the ionization principle or the fluorescent principle for quantitative measurement. A double window X-ray tube irradiates a pickup through filtration of a standard absorbing material from one window and irradiates another pickup through filtration by a test material. In this case, the X-ray source operates self-rectified; that is, raw high potential alternating current is placed across its elements, and the tube emits pulses of radiation for somewhat less than one-half cycle when the anode of the X-ray tube is positive with respect to the cathode. Thus, radiation pulses appear at the output terminals of the pickup devices simultaneously. These pulses are amplified and added algebraically with the resulting difference indicating the thickness difference between the master and the test material. It is quite difficult, if not impossible, to maintain dependable accuracy with this system due to the problem of maintaining constant and identical pickup outputs especially with the photoelectric type of pickup.

A third method utilizes two sources of X ray and one pickup device. This scheme is laid out in block form in Figure 3. In this case, both X-ray tubes are so arranged that their transmitted radiation after filtration from a master and a test piece, respectively, are applied to a single pickup device to enable subsequent electronic devices to differentiate between a standard signal and a test signal. The two X-ray tubes are so connected that they operate 180 degrees out of phase. Therefore pulses from each source arrive alternately at the common pickup. This method will be discussed in detail later.

The distance between the pickup and the X-ray source is important. The drop in intensity through air follows the inverse square law; thus, the intensity four inches away from the source would be 1/4 that of the intensity two inches away from the source. In order to keep the original intensity down to reasonable values for personnel safety and low X-ray tube loading, it is important that the pickup be kept near the source.

An Experimental Ionization Chamber Gauge

Much information and experience have been obtained in the X-ray gauging problem from work on an experimental ionization chamber thickness gauge. The basic scheme was that of number 2 mentioned previously; that is, one which used one X-ray source and two pickup units. The chamber only differed from common design in that a small acorn pentode vacuum tube was mounted in the

Figure 5. Gauge circuit used in the cold-mill thickness gauge

end opposite the beryllium windowed sensitive end. Dry air at atmospheric pressure was used as the ionizing medium.

The input circuit, Figure 4, utilizes the acorn pentode in an unorthodox manner to obtain electrometer tube operation. Usage and potentials of the various elements of the tube are such that absolutely no current is drawn from the ionization chamber by the control grid. The resistance values of $R1$ and $R2$ were in the order of 100 megohms to provide sufficient voltage for the control grid. The combination of $R3$, $R4$ and T acts as the differential comparator.

There are several obvious disadvantages of the ionization chamber type of thickness gauge as applied to an industrial layout. The output of the ionization chamber is extremely small; therefore, considerable amplification is necessary to obtain signals which can be handled in standard circuits. Thus, high gain amplifiers with their attendent difficulties are necessary. The high value of load resistance of the ionization chamber, together with its comparatively high capacity, combine to give a large time constant which will adversely affect the speed of response.

The Cold Mill Gauge

The Westinghouse X-Ray Division has recently completed development and design of an X-ray thickness gauge for cold mill application utilizing one photomultiplier pickup and two X-ray sources. The gauge, whose range is from 5 to 50 thousandths of an inch, attains accuracies up to 1 per cent.

The complete gauge consists of an X-ray source and pickup unit, a main-control housing, a remote control panel, and an indicator unit. The X-ray source and pickup unit consists of two separate X-ray sources and the housing for the photomultiplier tube. The main control housing contains all the necessary electronic equipment for the gauging operation together with auxiliary apparatus. Upon the remote-control panel the necessary controls for routine operation of the gauge are mounted. The indicator unit is the instrument which indicates thickness above or below the standard gauge being run. It contains a large switchboard type zero-center milliammeter and indicating lights for giving reject information.

The X-ray source consists of a self-contained oil immersed X-ray generator. The X-ray tube, which operates self-rectified, has a tungsten target. The tube current is maintained at 0.5 milliamperes and the tube voltage is varied between approximately 20 and 50 kilovolts, depending upon the gauge of steel being run. The pickup device which is the photomultiplier with a fluorescent screen surrounding its envelope is mounted in a brass housing located approximately two inches above the upper surface of the steel sheet. The standard X-ray source is located approximately ten inches horizontally from the photomultiplier. Its radiation is directed axially along a cylindrical brass X-ray cone through a standard sheet to the photomultiplier. The other X-ray source is located beneath the test sheet. Its radiation is directed upward through the sheet to the photomultiplier. The distances between the photocathode of the photomultiplier and the target of the two X-ray sources are equal. A photomultiplier is so mounted that a projection of its sensitive surface bisects the right angle formed by the intersection of the radiation from the two heads. Since in the cold mill application, X-ray source units and the pickup unit will be operating in an atmosphere with a heavy concentration of water vapor, oil, and scale, all electric connections are made waterproof. The control housing may be mounted in any convenient location up to 150 feet or more from the pickup unit. Each basically distinct circuit is wired in a separate chassis. These chassis are mounted on a rack which swings away from the front panel to facilitate accessibility to the wiring.

Interconnections between chassis are made with cable plugs to enable the serviceman to quickly change any particular unit that may need repair. These chassis contain the main gauge circuit and its power supply, a photomultiplier power supply, a selective reject circuit and a tandem-milliampere stabilizer.

The Gauge Circuit

The gauge circuit, Figure 5, consists essentially of a pentode-detector amplifier, a duplex diode clipper and base line restorer, a pentode saw-tooth converter and a pair of power amplifier pentodes used in a comparator circuit. A pentode photomultiplier stabilizer and a cathode ray indicator amplifier are also located in the gauge chassis.

The output signal obtained from the anode of the photomultiplier is capacitor-coupled to a conventional stage of pentode amplification. The amplified signal from the first stage is coupled to the clipper section of the duplex diode where a portion of the signal is conducted through to the following stage. The percentage of the signal amplitude which is conducted depends upon the bias maintained across the tube elements. This stage serves two purposes. Sensitivity selection is obtained simply by varying the bias across the elements. As more of the lower portion of the signal is clipped the percentage amplitude differential between the standard pulse and the pulse representing instantaneous pass-line thickness increases, thus increasing the thickness sensitivity. Thickness sensitivity is defined as the percentage thickness differential between the standard sample and the

Figure 6. Basic circuit used in the cold-mill gauge for stabilizing photomultiplier output

Figure 8 (left). Tandem milliampere stabilizer used for maintaining identical X-ray tube currents

Figure 9. X ray source and pickup unit for cold-mill thickness gauge

instantaneous pass line thickness which will give a full scale thickness indicator deflection. A second function of the diode is to prevent damaging currents from flowing through the indicator's movement in the event of large thickness differentials or complete removal of the pass-line strip.

The cathode of the clipper is coupled to a pentode saw-tooth convertor which in effect adds area to the pulses. The average value of the signal is quite small due to the short duration of the pulse thus the additional area derived from the saw-tooth wave form materially increases the effectiveness of the following stage.

The saw-tooth conversion is followed by the *6AG7* pair in a comparator circuit. This circuit operates in a somewhat unconventional manner. The control grids of the two tubes are in parallel. The cathodes are carried to ground through a potentiometer balancer and the gauge selector rheostat which is mounted in the control panel. The plates are carried through identical load resistors to $B+$. The screen grids are connected to the opposite ends of the secondary of a transformer whose center tap is grounded. Assume that at given instant pulse A has arrived at the control grid of the two tubes. At that same instant, the phasing of the alternating potentials on the screen grids are such that the left hand tube screen grid is at a positive peak. The right hand tube screen grid is 180 degrees out of phase, and thus at a negative peak. Since a pentode will not conduct when the screen is at zero or at a negative potential, no plate current will flow in the right hand tube. However, the left hand tube will conduct—the plate current being a composite a-c wave but instantaneously a current of a value depending upon the peak amplitude of the signal on the grid at that moment, the instantaneous alternating potential on the screen, and the tube characteristic. One-half cycle later, pulse B has arrived on the control grid. The right hand tube screen has become positive and the left hand tube screen has become the same value negative, and conduction occurs only in the right hand tube. Thus, the tubes become selective; the left hand tube operating with the pulse A and the right hand tube operating with pulse B. This circuit is in effect a bridge circuit in which the two plate load resistors and the two tubes act as the legs in the circuit. If a suitable instrument is placed between the two plates, any unbalance in the circuit will be indicated by a deflection proportional to the amount of unbalance. This unbalance, of course, will be caused by differences in amplitude of pulse A and pulse B. If the pulse amplitudes of A and B are equal, the voltage drops across the tube-plate resistors will be equal. Thus no direct potential will appear across the tube plates; however, if the pulse amplitudes differ, the plate currents of the two tubes will of course differ, thus, the voltage drop in the plate load resistors will differ and in effect a direct potential will appear across the tube plate and be indicated by the deflection in the proper direction of the indicating instrument. This indicating instrument is the instrument which indicates the thickness of the steel above or below the gauge of the standard piece. A high reactance choke is in series with the coils of the instrument to serve as a filter preventing alternating current from being applied to the movement.

The Photomultiplier Stabilizer

It is well known that high vacuum phototubes employing the secondary emission principle such as the *931-A* described previously are subject to drift in their characteristics. This drift occurs in varying degrees during tube operation and over the tube's life. Since this tube is the heart of the thickness gauge, it is apparent that the aforementioned drifts cannot be tolerated if the instrument is to remain accurate.

The circuit used in this particular gauge maintains phototube output constant by automatically controlling the dynode potentials and in effect controlling the tube's amplification. The photomultiplier picks up the signal from the visible light emitted by the fluorescent screen. The pulse is amplified throughout the phototube and then applied to one stage of external amplification. This pulse is then applied to a circuit which determines whether or not the amplitude is within the preset range. This compensator circuit then adjusts the power supply of the photomultiplier to a voltage output which will enable the photomultiplier to put out a signal of the predetermined standard amplitude. Thus, if the tube tends to drift to an increased amplification, the compensator circuit reduces the power supply voltage to the tube and the drift is automatically cancelled.

Figure 6 is used for a more detailed discussion. The circuit contains the following components: a photomultiplier tube, a standard pentode amplifier stage, a sharp-cutoff pentode, a π-filter network, a bias supply for the sharp-cutoff pentode, and a base-line restorer.

A pulse from the *931-A* is amplified by the pentode. This amplified pulse is applied to the grid of the stabilizer tube, which is the remote cutoff pentode,

through coupling capacitor $C1$. However, the stabilizer tube is biased far beyond cutoff, and thus it will not conduct unless the signal pulse amplitude nearly equals the d-c bias potential. If the stabilizer tube conducts, the average IR drop across R_k increases. Thus, the drop across $R1$ and $R2$ decreases. The pulse signal appearing across the tube is effectively filtered out by the π network of $C2$, $R3$, and $C3$. At times, the signal amplitude increases to quite high values due to thin test material or complete removal of the test material. This high signal amplitude will cause the grid to swing positive throwing the response beyond the linear portion of the grid characteristic with possible injury to the tube. The diode will tend to clip off the lower portion of the signal as seen by the grid of stabilizer tube, thus reducing the average a-c value. Since the average a-c value of the signal swings around the d-c-bias potential, the peak values will remain within the linear range. The base line reference is thus restored to its original position.

Calculations and experiments have shown that normal drift of any photomultiplier of the particular type under discussion easily can be compensated for by a maximum plus or minus variation of potential of 40 per cent across the eighth and ninth dynode. As shown in Figure 6, the dynode potential application is so designed that the seventh element is grounded. A constant high voltage supply feeds the bleeder from the seventh element to the cathode. The eighth and ninth dynodes are fed from the divider $R1$, $R2$, and the anode is supplied through a resistor from the common B supply for the vacuum tubes and the gauge circuit.

The signal input to the phototube is set originally so that an optimum signal current flows through the stabilizer tube. This sets the voltage across $R1$, $R2$ in its mid-value. If the tube tends to drift down in amplification, the pulse on the grid of the stabilizer tube becomes smaller. The voltage increases on $R1$, $R2$, and also on the eighth and ninth dynodes. The amplification increases again until the compensator circuit reaches equilibrium. Conversely, if the signal becomes too large due to a positive drift in $T1$, more voltage is peeled off the filter network. The eighth and ninth dynode potentials drop until balance is again obtained. Another desirable feature of this device is the fact that complete removal of the test sheet and the consequent subjection of high intensity radiation directly upon the pickup device does not injure the photomultiplier. The instant the test sheet is removed, the stabilizer automatically drops the eighth and ninth dynode potentials to a value low enough to prevent damaging currents from flowing.

This gauge as described is essentially a percentage reading device. However, the demands of industry are such that instruments of mensuration should not require conversion tables or conversion factors but must be of the direct reading type. There are certain circuit parameters which enable adjustment of sensitivity which subsequently could be used to obtain a direct reading instrument. The addition of a rheostat in the cathode circuit of the comparator provides a linear gauge selection control. Consequently, the operator may select the gauge of stock to be run by a simple adjustment of this calibrated rheostat at the remote control panel.

Selecting X-Ray Intensity

The X-ray source will be operating continuously, and thus the rating of the X-ray tube, which is generally the weakest link, must not be exceeded. The intensity of the X-ray beam is directly proportional to the current flowing in the X-ray tube and approximately proportional to the square of the voltage across the elements of that tube. Thus, in order to keep the losses down, it is possible to operate the tube at a very low current and obtain the intensity necessary for correct excitation of the photomultiplier by kilovoltage adjustment. In the cold-mill gauge, the X-ray tubes are operated at a constant current of one-half milliampere, with tube voltages varying from 20 to 50 kv dependent upon the gauge of the material being run.

Figure 7 shows the filtered X-ray intensity versus the thickness of a filtering medium at two different voltages. This plot shows logarithmically the change in filtered intensity due to a thickness change in the filtering medium, using equal initial intensities. This plot is derived indirectly from the exponential absorption equation. The wave length distribution, hence the absorption coefficient, is a function of tube voltage. It may be concluded from inspection of the curve or from inspection of the equation of the curve that the lower the voltage, the greater the sensitivity. A limitation exists, however, to prevent obtaining infinite sensitivity even under optimum conditions. The limitation arises first in the pickup device. This limitation is due to noise arising before the first stage of amplification in the photomultiplier. Statistical fluctuations in the number of incident X-ray quanta and dark current electrons arising in the initial stage of the photomultiplier result in this noise. Dark current is the weak output of a

Figure 10 (left). Control panel for cold-mill gauge

Figure 11. Main control housing showing instruments used for checking gauge operation

Figure 12. Thickness indicator shows thickness differential above or below standard directly in thousandths of an inch

photoelectric cell when no light falls upon it. This current arises from thermal emission and it could be reduced to negligible proportion by cooling the photomultiplier with liquid air or dry ice.

Optimum conditions include the use of the fluorescent screen causing the highest photomultiplier response, restriction of the X-ray beam to that small area on the fluorescent screen most effective in causing photomultiplier response, use of X-ray wave lengths for which absorption in the fluorescent screen is nearly complete, and use of a refined *931-A* for maximum light sensitivity.

It may be concluded then that for any given thickness of a certain material, there is one optimum kilovoltage for attainment of maximum sensitivity. The strict application of the absorption equation, however, is for monochromatic X rays only. In using a simple self-rectified X-ray generator with no filters as explained before, resultant X rays are heterogeneous in nature. Calculations corroborated by experiment have clearly shown that kilovoltage is not a highly critical factor in thickness gauge sensitivity due to wave length distribution as integrated over one pulse of radiation. Thus, voltage selection for a given gauge of material involves only two factors: One, obtaining a satisfactory optimum photomultiplier output and two, setting the photomultiplier stabilizer in the midpoint of its range.

The Tandem Milliampere Stabilizer

Operating the X-ray sources without any means of stabilization results in undependable gauge indication. X-ray tube current is dependent upon filament temperature, of course. If tube currents in the two heads are originally set at equal values, the possibility is quite remote that at the end of an hour's time the tube currents would still be equal. It is therefore necessary to automatically maintain identical current magnitudes at all times. This is accomplished with a tandem milliampere stabilizer. This electronic device maintains current equality by using current through one tube as reference and having the current of the other tube follow the former.

Briefly, the stability is obtained by comparing the two currents and using the voltages produced in the comparison to bias a control tube which varies the magnitude of a series reactance in one filament power supply which we may call the slave tube. Thus, if the slave current changes with respect to the reference or, master, the bias on the control tube will change in such a manner as to adjust the reactance to a new value which will in effect allow the correct anode current to flow. Referring to Figure 8, the operation briefly follows. Anode current from each tube is brought to ground through two equal resistors. Potentials proportional to the two currents are picked off *R*1 and *R*2 and rectified by a duplex diode, which prevents the negative portion of current wave due to distributed capacitance in the transformer winding from entering the comparison. This diode charges capacitor *C*1 and *C*2 to voltages proportional to their respective currents.

Rheostats *R*3 and *R*4 adjust the time constants of the two *RC* circuits which enable the operator to vary the magni-

Figure 13. Service is facilitated by dividing the various basic circuits into separate chassis and using plug and cable connections between chassis

Circuit operation may be checked by inserting the milliammeter plug into jacks located in various stages

tude of the slave current. The bias on the control grid of the pentode is the algebraic sum of the two capacitor voltages and the bias battery voltage. This pentode is preferably one of high transconductance such as the *6AG7*. Plate current flows through the d-c winding of a saturable reactor. It can be seen that the alternating voltage drop across the reactor is controlled directly by the plate current of the pentode; that is, the greater the plate current, the smaller the voltage drop which results in a higher current in the slave tube. If anode current in the master tends to increase, voltage across *C*1 will increase tending to make the grid more positive which in turn allows more plate current to flow. This condition reduces the voltage drop across the reactor, thus increasing current in the slave to a point where balance is again obtained. An antihunt device using a feed-back transformer and a duplex diode rectifier, capacitor coupled to the grid circuit prevents oscillation due to high sensitivity and quick response to small current changes.

The entire X-ray generator is stabilized by an induction regulator. Voltage applied to the X-ray tubes must be carefully equalized to obtain coincident intensities of the resultant heterogeneous radiation. The variation in inherent filtration of the X-ray generators themselves due to slight differences in X-ray tube window thickness, oil surrounding the tube and head window thickness result in slight deviations from equality with equal increments of kilovolt change on the two X-ray tubes. Therefore, with changes of thickness of stock to be run, which require changes in tube voltage, slight rebalancing is usually necessary. With matched heads, these changes are so slight that a small X-ray current adjustment will satisfactorily correct output intensities with no adverse effects to accuracy. The addition of a solenoid operated slide mechanism, which inserts a preselected gauge of stock into the test beam, enables quick checks on gauge calibration. This device is mounted directly above the test sheet head.

An electronically-operated reject circuit operates from the output of the comparator circuit. The relays operated from this circuit close at predetermined thickness differentials for operation of reject mechanisms, alarm bells, or lights.

Personnel Protection

The question is often asked "What danger exists from X radiation to the operating personnel?" In the cold-mill gauge, there is no way possible for the operating personnel to be directly exposed to the primary radiation. The only danger that might exist is from the refracted and reflected X rays or scatter. The direct radiation is of an intensity low enough that the scatter radiation two inches from the point of the test sheet being irradiated is of an intensity much lower than the maximum dosage rate as given by the American Standards Association. In a hot-mill gauge, where the steel thicknesses are sometimes over a quarter of an inch, and the X-ray source-to-test sheet distance must be quite large due to the temperature of the sheet, the intensity of scatter will be proportionately greater. However utilization of proper protective means will eliminate any danger. The X-ray thickness gauge as in any X-ray application must utilize personnel protection proportional to the power of the generating unit involved.

Other Gauge Applications

There are hundreds of applications for an X-ray thickness gauge. Among them are measurement of the thickness of linoleum, plastic, sheet glass, many types of sheet metal, and paper and cardboard. One interesting application of a gauge which wouldn't work was that of counting bank notes. The bank notes were to be in bundles of 100, 500, or 1,000. The thickness gauge was required to indicate the number above or below that standard number in a given bundle. It sounded simple until it was found that the thickness of single bills was not uniform. They varied ±10 per cent. Thus, the indication as given by the gauge for the extreme condition would be 10 per cent from the actual number in the bundle.

The gauging of glass container wall thickness is readily accomplished with a variation of the cold-mill X-ray gauge. This application consists of scanning the container's wall with the object of locating thin portions which would tend to reduce the strength of the container.

Conclusion

Although each geometrical system has certain advantages over the others, it has been found that the two-source one-pickup system offers outstanding advantages in stability and precision. The photomultiplier pickup, sometimes of questionable value as a precision device, becomes a remarkably accurate instrument for quantitative radiation mensuration when properly selected and stabilized.

The combination of properly designed gauge and auxiliary electronic circuits and the remarkably adaptable photomultiplier pickup makes the X-ray gauge an important new tool in many manufacturing processes and industries.

Suddenly Applied Loads Carried by a Variable-Ratio Synchronous–Induction Frequency Changer

A. G. DARLING
MEMBER AIEE

G. A. KAUFMAN
NONMEMBER AIEE

Synopsis: The induction machine of this frequency changer has demonstrated its ability to start and carry rotating machine induction loads requiring 140 per cent of the kilovolt-amperes of the induction machine to start them without benefit of capacitive excitation. A-c amplidynes are used for automatic voltage regulation of the induction machine. D-c amplidynes are used for regulating the load through the frequency changer. So far as the authors are aware, this is the first commercial installation of this type to incorporate these features.

General Conditions

THE PITTSBURGH WORKS of the Jones and Laughlin Steel Corporation generates its own power at 25 cycles and 6,600 volts. The power house includes three 20,000-kw and one 10,000-kw turbo-generators.

The power demand at the plant is as high as 46,000 kw. The major single item of this load is the hot strip mill. Every minute or so, when this mill is in operation the load rises 20,000 to 25,000-kw in five to seven seconds, stays at that level for three to five seconds, and then is reduced by the same amount in five to seven seconds. Among other loads, there is approximately 5,000 kw of essential load, such as the water supply pumps and so forth. Any interference which cuts off the power supply to this essential load, may cause heavy damage to the plant equipment. For instance, the water-cooled furnaces, deprived of water, may be put out of commission for a long period of time with an immeasurable financial loss to the steel company.

The company's power house is located in the flood danger zone. While it is not very probable, it is still possible that an extremely high flood would shut down the power house entirely, endangering the servicing of the essential load.

It was decided, therefore, to provide a tie with the Duquesne Light Company in order: (*a*) to obtain some 5,000-kw emergency service for essential loads in case the Jones and Laughlin power house should be shut down, and (*b*) to take a certain share of the total mill load.

Since the power company's system is 60-cycle, a frequency changer is required to provide the necessary link between the two systems. From the foregoing requirements it is obvious that the frequency changer should be capable of supplying, in emergency cases, the 25-cycle essential load acting at that time as a stub feed. At other times, the frequency changer should permit the regulated flow of power from the 60-cycle to the 25-cycle system, as required. The reverse flow of power from the 25-cycle steel company's power system to the 60-cycle public utility, is possible although it is not essential for this installation.

The power contract is such that it is advantageous to take power at a constant-demand rate. Without some form of control of the power flow through the frequency-changer set, a fairly large proportion of the load changes of the steel mill would be passed on to the public utility. For this reason, control of power flow through the set becomes an economic feature.

Selection of Type of Frequency Changer

At least three types of frequency changer sets were available: the synchronous-synchronous, the electronic, and the variable-ratio induction—synchronous set with, in this case, Scherbius control of the variable ratio.

In this instance, dimensions, weights, and efficiencies entered into the selection to only a minor degree. The characteristics which appear to control the selection can be briefly stated.

The fixed ratio or synchronous–synchronous set, would pass on to the power company a major portion of the load changes occurring in the steel plant. In order to control load changes through the frequency changer set, use of this type of frequency changer would necessitate control of the steel plant power generation in terms of the load through the frequency changer set, because there was no hope of controlling the generating sources of the large, widely dispersed public utility system. To accomplish the control of the four steel plant generators totaling 70,000 kw, it would have been necessary to equip their inlet steam valves with servomotors and make sure that the boiler pressure was not varied too fast or too widely. This would have been an expensive and somewhat intricate control to be certain that the steel plant generators not only took the load, but took it in proportion to their individual ratings. The synchronous–synchronous set is perfectly capable of furnishing stub-feed load and reactive kilovolt-amperes to either frequency system.

The electronic[1] set differs widely from the rotating types of frequency conver-

Manuscript submitted November 12, 1947; made available for printing December 19, 1947.

A. G. DARLING is a member of the industrial power division, industrial engineering divisions of the General Electric Company, Schenectady, N. Y. and G. A. KAUFMAN is chief electrical engineer, Jones and Laughlin Steel Corp., Pittsburgh, Pa.

To P. W. Robinson and F. N. Bauman goes the credit for the design of the frequency changer and to F. E. Crever (M '45) for the design of the rheostatic voltage and amplidyne voltage and load regulators. J. D. Neeley and J. E. McNamara (A '45) supervised the installation and testing of the entire equipment.

ters. An electronic converter passes power through it to the system of the lower voltage and in proportion to the deviation from the nominal voltage ratios of the two systems. The flow of power through the frequency changer can be controlled by observing its direction and amount and modifying the grid firing angle to correct for deviation from the desired power flow. Some developmental design would be required to make it serve a stub feed load at either frequency. This equipment, for stub-feed operation, requires a-c excitation for both the rectifier and the inverter which takes the form of synchronous condensers operating on each frequency and equipped with starting motor of opposite frequency. When operating in parallel with other synchronous generators and motors, these machines can supply the necessary a-c excitation provided their capacity, in that respect, is not already used. These additional features for the electronic converter make it more expensive and less applicable for this installation.

The induction–synchronous variable-ratio frequency changer, when supplied with Scherbius type of excitation for the induction machine, can have its frequency ratio varied and can also supply stub-feed load from both the induction and the synchronous ends. When connected between two generating systems, the load through the set can be kept constant by varying the slip of the induction motor through the Scherbius control. In this case, the variable-ratio Scherbius-frequency changer set met all the conditions of the installation.

Accordingly, a 12,500-kw size set, Figure 1, whose major machines have been successfully used for a number of years at the Hudson Coal Company's plant near Wilkes-Barre, Pa., was found to apply adequately for the Jones and Laughlin installation. This set consists of a 15,000-kva 0.9 power factor, 13,800-volt, 60-cycle synchronous motor; a 13,500-kva 1.0 power factor, 6,600-volt, 25-cycle induction generator; a 1,200-kva Scherbius regulating machine and 33-kva a-c exciter and a 60-kw, 250-volt, d-c exciter for the synchronous motor. Amplidyne load and voltage regulators, capable of compensating for rapid changes constitute portions of the full automatic control of the frequency changer.

Power System

The power system of the Jones and Laughlin installation is illustrated in Figure 2. This diagram shows the frequency changer set located at the cold-strip mill connecting it to the public utility system.

Figure 1. The 12,500-kw 25–60-cycle 514-rpm Scherbius frequency changer set in the cold strip mill of the Jones and Laughlin Steel Corporation at Pittsburgh, Pa.

Results of Operation

Since the set was put into operation in November 1946, it has carried $28^1/_2$ per cent of the total mill load in kilowatt-hours at an average capacity factor of $46^1/_2$ per cent and a maximum capacity factor of 107 per cent in one month. During a shortage of steam for the turbine generator plant, the set was a major factor in maintaining steel production.

Figure 3

Figure 4

Induction Machine Carries Stub Feed Load

Tests have been made to indicate the ability of the induction-Scherbius portion of the set to carry stub feed load. To substantiate expectations,[2,3] two sizes of synchronous motor-generator sets were started from rest by energy from the induction generator of the frequency changer. These two motors, rated 2,200 and 3,900 kva, require approximately 10,000 and 19,000 starting kva, respectively, at rated voltage. In the test, full voltage from the induction generator at normal frequency was applied and supported by the a-c amplidyne and rheostatic-type regulators with high speed resistance and shorting contactors. The resulting voltage and frequency are shown in the charts of Figure 3.

It will be noted that the starting kilovolt-amperes of the motors is approximately 75 per cent and 140 per cent of rated kilovolt-amperes of the induction generator. So far as is known, this is the first occasion on which a stub-feed load has been started and run from an induction generator.

Load Control Maintains Constant Demand

Automatic load control of the frequency changer is such that it tends to hold a constant demand on the 60-cycle power supply and is used only under parallel operation of the frequency changer with the 25-cycle turbine generators—both sources serving a common load. Since the load regulator tends to hold a constant load through the frequency changer, variations in the load are ultimately taken by the 25-cycle turbine generators. The inherent speed regulation (less than 1 per cent slip) of the induction machine of the frequency changer is much narrower than the speed regulation (more than 4 per cent) of the 25-cycle turbine generators. The unequal regulation of these sources causes the frequency changer to increase or decrease its load as the 25-cycle system load increases or decreases. The load regulator[4,5] detects these changes and respectively causes the frequency changer to decrease or increase its load, so forcing load increases or decreases on the steam-turbine generators. These effects are shown in the high speed charts of Figure 4. Under these variable conditions of loading the regulator controls the integrated demand to a predetermined, constant value.

Influence of the Core Form Upon the Iron Losses of Transformers

G. M. STEIN
MEMBER AIEE

Synopsis: The effect of the magnetic field distribution upon the iron losses of transformers is represented in practical formulas for the examples of core- and shell-type single-phase punching cores, and of the 3-phase core-type core. This computation furnishes as much as 13.5 per cent lower core losses, as compared with previous conventional methods. In another application, it is shown that a widening of the yokes permits only a relatively small reduction in losses.

FOR the computation of the iron losses in transformer cores, the designer knows the specific losses obtained under a uniform magnetization in an Epstein test. In the finished product, these values are increased by the handling and machining of the material, as well as by the stray losses in end frames and tank.[2] The losses also will rise in a magnetization directed perpendicularly to the grain orientation. The loss calculation becomes further complicated since the field is uniform only in the center part of the leg. The yokes, however, and especially the corners between yokes and legs, contain a quite heterogeneous flux distribution, as shown in Figure 1. This condition usually is taken care of by separating the core into legs and yokes, and by estimating a division of the corners between these two areas. The losses are computed for a uniform field in both parts.

This approximation has its definite limitations. If applied, for example, to the yokes, the flux density and losses appear to decrease towards zero for a very large widening, while actually the yoke losses remain a definite quantity, as shown in Figures 7 and 18 of this paper. For equal yoke and leg sections, however, the approximation becomes the product of the total core weight and of the specific losses in the leg center. The real losses, however, may be more than ten per cent smaller than this result since the corners of the yokes are only partly filled with a flux of higher density.

In order to compute the iron losses with sufficient accuracy, the actual field in the core has to be considered. Such an analysis already has been made in a previous article[3] where the results are given in the form of curves. It shall be the object of the present paper to improve the accuracy of that calculation, and to convert its curves into simple formulas for the use of the designer. For this purpose, an expression for a fictitious core weight will be developed, whose product with the specific loss in the leg center represents the total iron loss. This particular weight is different from the actual core weight, and shall, therefore, be distinguished as the "core loss weight." It is computed on the basis of the geometrical dimensions of the core, and of the specific magnetic properties of the core material.

Figure 1. Field distribution in the corner of a transformer core

Derivation of the Losses From the Flux Distribution

For finding the relationship between flux distribution and core losses, introduce

L = total core losses (watts)
w = specific core losses (watts/lb.)
K, θ = material constants of core
ϕ = core flux (Maxwells)
B = magnetic flux density (kilogausses)
φ = total magnetic potential drop in core
μ = permeability of core material

The quantity w depends on B in every point of the core, according to the loss curve of the material. Each small part of this curve can be represented by the equation

$$w = (KB)^\theta \tag{1}$$

in which K and θ are material constants, and vary with B, as shown, for example, in Figure 2 for transformer sheet steel. Between $B=6$ and 15, the exponent θ is increasing in this chart from 1.6 to 2.7, and reaches an average of $\theta=2$ at $B=12$. If this value of θ is used in the analysis, the corresponding expression

$$w = K^2B^2 \tag{2}$$

for the specific iron losses w assumes the same form as the specific copper losses

$$w_c = (1/\rho)J^2 \tag{3}$$

in a conductor, Figure 3, of the resistivity ρ with the current density J. Consequently, this current flow can be compared with the magnetic field in the core if the density J corresponds to B and if the material constant $1/\rho$ is the equivalent of K^2. In addition to this, the current I and the voltage drop E of the conductor have to be replaced by the flux ϕ and by the potential drop φ in the core, as shown in Figure 4, in order to change the conductor losses

$$L_c = EI \tag{4}$$

Paper 48-18, recommended by the AIEE transformer committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26-30, 1948. Manuscript submitted November 10, 1947; made available for printing December 22, 1947.

G. M. STEIN is design engineer with Westinghouse Electric Corporation, Sharon, Pa.

Figure 2. Loss values of transformer sheet steel for 60 cycles

into the core losses

$$L = C\phi\varphi \tag{5}$$

where C is a quantity depending on the units of ϕ and φ.

Although the permeability μ of the core varies considerably from point to point, consider μ as constant since this approximation agrees with test results.[3] The constant μ may be included in C by changing the units of φ, so that φ is coordinated to ϕ under the condition $\mu = 1$. Such a drop φ represents only a quantity introduced for loss calculations, and should not be mistaken for the magnetomotive force in the iron.

Definition of Core Loss Weight and Core Loss Length

In order to fill out the cylindrical space inside a circular coil, the transformer core usually is composed, as in Figure 5, of a number of layers of different rectangular sections (I) to (V), whose losses can be computed separately. Consequently, confine the analysis to a core with rectangular section, and start with the single-phase core-type construction, Figure 4, by introducing

a, d = width of leg and yoke sections (inches)
h = depth of core (inches)
$A = ah$ = area of leg section (square inches)
b, c = height and width of core opening (inches)
S = iron space factor
D = density of iron (pounds per inch³)
G = core weight (pounds)
G'' = core loss weight (pounds)
l = effective mean core length (inches)
l'' = core loss length (inches)
$\lambda = d/a$ = yoke widening factor

Because of μ = constant, the reluctance

$$R = \varphi/\phi \tag{6}$$

of the magnetic path inside the core becomes independent of the strength of the magnetization, and is determined only by the geometrical dimensions. Therefore, eliminate φ from the equations 5 and 6, and obtain

$$L = CR\phi^2 \tag{7}$$

From now on, let w and B describe the values in the center leg section only, and substitute the equations 2 and

$$\phi = 10^2 BA(2.54)^2 S \tag{8}$$

into equation 7, to find

$$L = \left(\frac{10^6(2.54)^4 C}{K^2} RA^2S^2\right)w \tag{9}$$

Apply this formula to a unit cube in the center of the legs, that is, replace

$$RA^2 = 1$$

and

$$L = DSw$$

in equation 9, and obtain

$$10^6(2.54)^4 C/K^2 = D/S$$

which furnishes

$$L = (DRA^2S)w \tag{10}$$

Figure 3. Schematic diagram of the current flow in a conductor

The coefficient of w depends only on the geometrical dimensions of the core, and on the density of its material, and has the dimension of a weight. Consequently, introduce that factor as the "core loss weight"

$$G'' = DRA^2S \tag{11}$$

and write

$$L = G''w \tag{12}$$

Furthermore, define a flux ψ per unit core depth by

$$\phi = h\psi \tag{13}$$

so that the equation 6 appears as

$$R = \left(\frac{\varphi}{\psi}\right)\frac{1}{h} \tag{14}$$

Since only the ratio φ/ψ enters the calculation, one component φ or ψ can become a freely chosen constant. In line with the field analysis of Appendix I, use $\psi = \pi$, that is, substitute

$$R = \frac{\varphi}{\pi}\frac{1}{h} \tag{15}$$

into equation 11, and find

$$G'' = DASa(\varphi/\pi) \tag{16}$$

The corresponding actual core weight G is derived from an effective mean core length l as[1]

$$G = DASl \tag{17}$$

By a comparison of these two equations, a corresponding fictitious core length l'' can be defined for the computation of G'', and becomes the "core loss length"

$$l'' = a(\varphi/\pi) \tag{18}$$

if equation 16 is changed into

$$G'' = DASl'' \tag{19}$$

Calculation of Core Loss Weight and Core Loss Length

By equations 16 and 18, the calculation of G'' and l'' is reduced to that of the potential drop φ around the core, whereby φ is referred to a flux $\psi = \pi$ per unit depth and to a permeability $\mu = 1$. The quantity φ shall be derived first for the single-phase core-type core since this model is the basis of other core forms.

For reasons of symmetry, only one quarter MNO_1PQO_2 of the core has to be considered, as shown in Figure 6. In this quarter core, separate the drop 1/4 φ into φ_1 of the uniformly magnetized portion of the leg and into the rest φ_2 up to the middle of the yoke.

The core region assigned to φ_1 extends up to H at a distance a from the lower edge of the yoke, since below this point the magnetic field in the leg is sufficiently uniform.[3,4] Introduce the length

$$l_1 = (1/2)b - a \tag{20}$$

Figure 4. Schematic diagram of the magnetic circuit in a single-phase core-type core

Figure 5. The rectangular components of a circular core section

of this leg area into equation 18, substitute φ_1 for φ, and obtain

$$\varphi_1 = \pi\left(\frac{b}{2a} - 1\right) \tag{21}$$

The other component φ_2 can be read from the chart, Figure 7, taken from a previous publication[3] and analyzed in Appendix I. The amounts of φ_2 are given as a scale on the center flux lines for different values of the yoke widening factor λ between $\lambda = 0.8$ and ∞. The points of equal φ_2 are connected by curves. The values of $(1/2)\ (c/a)$ are marked on the lower edge of the yoke so that φ_2 can be obtained for any given quantities of a, c, and λ.

In order to convert this chart into practical formulas, the core area is divided, as shown in Figure 6, into yoke, leg, and corner by the x, y co-ordinate system in the corner point O_1. Individual potential drops φ_n, φ_j, φ_c are assigned to these three parts, and will be computed on the basis of Figure 7.

This chart has been derived under the assumption of very long legs and yokes, and of a uniform magnetization at their center lines MN and PQ in Figure 6. Such an approximation, in general, will be satisfactory in the leg, but not in the yoke where a noticeable error is introduced.

For finding the magnitude of this error, φ_2 has been determined in Appendix I also for a finite yoke length and for the two special cases of $\lambda = \infty$ and $c = 0$. The results are plotted in Figure 18 against c/a and λ, respectively, and are compared with the corresponding amounts obtained from Figure 7 for a single corner region.

For $\lambda = \infty$, these curves reveal a constant error of 0.42 potential unit in the single corner values for the practical range between $c/a = 0.5$ and 4.0. The amount of 0.42 represents in this range the maximum possible discrepancy, since the error decreases with λ, and, as shown in Figure 18, is reduced for $c/a = 0$ from 0.70 at $\lambda = \infty$ to 0 at $\lambda = 0.75$. Consequently, the error will remain practically independent of c/a also at finite values of λ. For this reason, the correction can be made in Figure 7 at the y axis where φ_2 represents only part of the quantity φ_2 of Figure 6, and is reduced from 5.22 to 4.80 for $\lambda = \infty$, but retains its value of 4.73 for $\lambda = 0.75$; that is, a constant amount of 4.80 can be chosen for this φ_2 in the whole practical range of λ. This correction must lie also somewhere between the results obtained at the y axis from the chart, Figure 7, that is, for $c/a = \infty$, and from the calculation made for $c/a = 0$. By using the average, shown in Figure 18, find again a constant $\varphi_2 \cong 4.80$ for all desirable values of λ.

Figure 6. Sectionalization of a single-phase core-type core for loss calculations

The rest of the φ_2 in Figure 6 is the yoke drop φ_x which appears in Figure 7 between $x = 0$ and $-1/2\ c$, and which is plotted in Figure 8 against x/a replacing $-x/a$. In a uniform yoke field, find instead a potential function

$$\varphi_{ox} = (\pi/\lambda)(x/a) \tag{22}$$

For sufficiently large values of x/a, as, for example, for $x/a = 1.0$, the slope of φ_x will go over asymptotically into the direction of φ_{ox}. Consequently, approximate φ_x by its tangent line at $x/a = 1.0$ which intersects the ordinate at φ', as shown in Figure 8 for the example $\lambda = 2.0$, and write

$$\varphi_x = \varphi' + \varphi_{ox} = \varphi' + (\pi/\lambda)(x/a) \tag{23}$$

The component φ' is independent of x/a, that is, it becomes a function of λ only, which can be approximated, in the practical range between $\lambda \cong 0.8$ and 4.0, by the straight line

$$\varphi' = 0.25(\lambda - 0.9) \tag{24}$$

as shown in Figure 9.

The total drop φ_2 in Figure 6 is then composed of the drop 4.8 up to the y axis and of φ_x so that equations 23 and 24 furnish

$$\varphi_2 = \frac{\pi}{2\lambda}\frac{c}{a} + \varphi' + 4.8 \tag{25}$$

By adding φ_1 of equation 21 to this φ_2, find the total drop $1/4\varphi$ in the quarter core MNO_1PQO_3

$$1/4\varphi = \frac{\pi}{2}\frac{b}{a} + \frac{\pi}{2\lambda}\frac{c}{a} + 1.44 + 0.25\lambda \tag{26}$$

which may also be written, according to Figure 6,

$$1/4\varphi = \varphi_n + \varphi_j + \varphi_c \tag{27}$$

Consequently, define

$$\varphi_j = \frac{\pi}{2}\frac{b}{a} \tag{28}$$

as the drop in the leg portion of the quarter core for a uniform leg field, and introduce

$$\varphi_j = \frac{\pi}{2\lambda}\frac{c}{a} \tag{29}$$

as the corresponding drop in a uniform yoke field. The rest, that is,

$$\varphi_c = 1.44 + 0.25\lambda \tag{30}$$

is independent of the opening dimensions b and c and, therefore, shall be identified as the corner drop although this φ_c repre-

Figure 7. The potential chart of a single corner region

Figure 8. The potential drop in the yoke

sents more than the actual share of the corner.

This result can be checked with the field distribution derived by S. Bergmann[4] in which he considers the actual shape of the area of MNO_1PQO_2 of Figure 6. As example, he uses the extreme case of a relatively small square opening with $b/a = c/a = 0.725$ and $\lambda = 1$, and obtains $\varphi = 16.24$ as compared with $\varphi = 15.84$, computed by equation 26.

The equations 18 and 26 furnish the core loss length

$$\left.\begin{aligned} l'' &= 2[b + c/\lambda + k''a] \\ k'' &= 0.92 + 0.16\lambda \end{aligned}\right\} \text{for } \theta = 2 \tag{31}$$

of a single-phase core-type core, as compared with its effective mean length[1]

$$\left.\begin{aligned} l &= 2[b + \lambda c + ka] \\ k &= 2\lambda \end{aligned}\right\} \tag{32}$$

whereby the contribution of the corners is described by the constants k and k''.

For extending the calculation of l'' for $\theta = 2$ to any θ, consider l'' as being composed, like φ, of three separate contributions b, c/λ, and $k''a$ of legs, yokes, and corners. Since the contributions of yoke and leg have been arrived at under the condition of a uniform magnetization, they can be computed for any θ, and the equation 31 will be improved to that extent. For this purpose, let w and B continue to describe the specific losses and flux density in the leg, while w_j and $(1/\lambda)B$ represent the corresponding values in the yoke, and write, according to equation 1

$$\left.\begin{aligned} w &= (KB)^\theta \\ w_j &= (KB/\lambda)^\theta \end{aligned}\right\} \tag{33}$$

Since the actual weights G_s and G_j of legs and yokes, defined by Figure 6, are given by

$$\left.\begin{aligned} G_s &= 2AbSD \\ G_j &= 2\lambda AcSD \end{aligned}\right\} \tag{34}$$

their combined losses $L_a = G_s w + G_j w_j$ become

$$L_a = ASD2[b + (\lambda)^{1-\theta}c]w \tag{35}$$

According to a comparison with equations 12 and 19, consider

$$l_a'' = 2[b + (\lambda)^{1-\theta}c] \text{ for any } \theta \tag{36}$$

as the resultant core loss length of legs and yokes. Substitute its value in place of

$$l_a'' = 2[b + c/\lambda] \text{ for } \theta = 2 \tag{37}$$

in equation 31, and find

$$\left.\begin{aligned} l'' &= 2[b + (\lambda)^{1-\theta}c + k''a] \\ k'' &= 0.92 + 0.16\lambda \end{aligned}\right\} \tag{38}$$

Figure 9. The constant component of the yoke potential

for the single-phase core-type core and any θ. Note that l'' becomes independent of θ for $\lambda = 1$.

On the basis of this result, l'' can be derived also for other types of punching cores.

As second example, consider, therefore, the single-phase shell-type core, Figure 10.

If this shell-type core has widened yokes, but unwidened outer legs, that is, for $d = \lambda(a/2)$ and $e = a/2$, it can be considered as composed of two core-type cores, Figure 6, of half the iron section. Consequently, the weight of the shell-type form becomes identical with that of a core-type constuction of the same opening and iron section if the corner weight is cut in half. Under this condition, derive from the equations 32 and 38

$$\left.\begin{aligned} l'' &= 2[b + (\lambda)^{1-\theta}c + k''a] \\ k'' &= 0.45 + 0.08\lambda \end{aligned}\right\} \tag{39}$$

as compared with

$$\left.\begin{aligned} l &= 2[b + \lambda c + ka] \\ k &= \lambda \end{aligned}\right\} \tag{40}$$

for the single-phase shell-type form with unwidened outer legs.

For equally widened yokes and outer legs, that is, for $d = e = a/2$, divide the shell form (Figure 10) into the center part between the lines $A-A$ and $B-B$ and into the region outside these lines. The center part has the same shape as before so that it will contribute to l'' and l half the values of equations 39 and 40. The outside region has the same widening λ in legs and yokes; that is, it has to be treated like one-half of an unwidened shell-type core of the center leg width λa. Consequently, develop

$$l'' = b + (\lambda)^{1-\theta}c + (0.8\lambda + 0.46)a + (\lambda)^{1-\theta}[b + c + (0.46 + 0.8)\lambda a]$$

and

$$l = b + \lambda c + \lambda a + \lambda[b + c + \lambda a]$$

into

$$\left.\begin{aligned} l'' &= 2\left[\frac{1 + (\lambda)^{1-\theta}}{2}b + (\lambda)^{1-\theta}c + k''a\right] \\ k'' &= 0.23 + 0.04\lambda + 0.27(\lambda)^{2-\theta} \end{aligned}\right\} \tag{41}$$

as compared with

$$\left.\begin{aligned} l &= 2\left[\frac{1 + \lambda}{2}b + \lambda c + ka\right] \\ k &= (1 + \lambda)\lambda/2 \end{aligned}\right\} \tag{42}$$

for the single-phase shell-type core with equally widened yokes and outer legs.

The 3-phase core-type core, shown in Figure 11, is magnetized in the center leg (I) and in the two U-shaped outside parts (II) and (III) like a single-phase core.

Figure 10. Schematic diagram of the single-phase shell-type core

Figure 11. Schematic diagram of a 3-phase core-type core and of its single-phase flux components

In the two areas $\Delta = ORST$, the magnetization is rotating, but causes about the same losses as in a pulsating field.[5] In the special case of $\theta = 2$, these losses can be computed, according to Appendix II, as the sum of the losses in the single phase α and β fields, Figures 11 and 12.[11]

The α field of Δ is identical with the distribution above the center leg of a shell-type core of the yoke widening 2λ so that the drop φ_α in each Δ is furnished by equations 30 and 72 as

$$\varphi_\alpha = \varphi_c/2 + 0.72 + 0.25\lambda \tag{43}$$

The corresponding drop φ_β in each Δ is derived in Appendix II in terms of a drop φ_u over a distance a in a uniform β field of the yoke. φ_u is obtained from φ_f in equation 29 by interchanging $c/2$ with a. Since the flux in the β field is only 86.6 per cent of the 3-phase flux, φ_u must be reduced also by the ratio of the corresponding losses. Consequently, substitute

$$\varphi_u = 0.75\pi/\lambda \tag{44}$$

into equations 74 and 75, and obtain

$$\varphi_\beta = \varphi_u(1-\sigma) = 2.36(1-0.15\lambda)/\lambda \tag{45}$$

According to equations 43 and 45, each Δ space will contribute a resultant drop

$$\varphi_\alpha + \varphi_\beta = \begin{Bmatrix} 0.72 + 0.25\lambda + 2.36/\lambda - 0.35/\lambda^2 \\ 2.98 = 0.95\pi \text{ for } \lambda = 1 \end{Bmatrix} \tag{46}$$

to the total drop in the 3-phase core, that is, for $\lambda = 1$, this contribution is 5 per cent lower than the corresponding drop π in a uniform field carrying the full leg flux. This difference becomes even smaller for higher λ, and will cause an error of less than 1 per cent in the total losses since the Δ space represents in the average only 10 per cent of the whole core. Consequently, assume a uniform Δ field of the same size as in the yokes, and extend its loss calculation to any θ.

The value of l'' of the 3-phase core, Figure 11, then will be equal to that of a single-phase core-type core, Figure 6, of the same opening and core section, plus the core loss length of one leg, two yokes,

Figure 12. The single-phase flux components in the Δ space of a 3-phase core

and the two regions Δ. Consequently, derive from equation 38

$$\left.\begin{aligned} l'' &= 3[b + 1.33(\lambda)^{1-\theta}c + k''a] \\ k'' &= 0.61 + 0.11\lambda + 0.67(\lambda)^{1-\theta} \end{aligned}\right\} \tag{47}$$

as compared with

$$\left.\begin{aligned} l &= 3[b + 1.33\lambda c + ka] \\ k &= 2\lambda \end{aligned}\right\} \tag{48}$$

for the 3-phase core-type core.

Numerical Applications

In a comparison of the foregoing loss calculation with present conventional methods, use first the example of a 100-kva single-phase shell-type core, Figure 10. Its numerical data are $a = 5^3/_8$; $h = 7^{15}/_{16}$; $b = 12^1/_4$; $c = 4^3/_{16}$; $\lambda = 1$; $D = 0.271$; $S = 0.89$. Because of the unwidened yoke, any conventional method will furnish L as the product of G and w, as compared with the product of G'' and w, introduced in equation 12 for a loss calculation by flux distribution; or the ratio of the losses obtained by the old and new methods will be equal to the ratio of G to G''. Consequently, compute from equations 17, 19, 39, 40 the values $l'' = 38.23$; $G'' = 392$ in relation to $l = 43.38$; $G = 445 = 1.135\ G''$; that is, the conventional way leads to 13.5 per cent higher losses than derived from the actual flux distribution. If such a conventional calculation is compared with test results, some of the stray losses in end frames, tank, and other sources will be considered erroneously as part of the core losses, and will remain undetected.

As a second example, the problem of how much L can be decreased with an increase of λ already has been solved for the single- and 3-phase cores, Figures 4 and 11, and for $a = c$ and $b = 5c$ in a previous publication.[5] In this paper, the losses are computed on the basis of the actual flux distribution, as given by the chart Figure 7, and also in a conventional way for a uniform field where the core is divided into legs and yokes by the x axis, Figure 6. The results are cited in Figures 13 and 14, where the per cent decrease ΔL of the

Figure 13. Loss change with yoke widening in a single-phase core-type core

1—From chart, Figure 7
2—Conventional method

(a)—B = 10 kilogausses
(b)—B = 12 kilogausses
(c)—B = 15 Kilogausses

losses is plotted against the per cent increase $\Delta\lambda$ and ΔG of λ and G.

In the single-phase example, Figure 13, and for $\Delta\lambda = 40$ per cent or $\Delta G = 15$ per cent, the field distribution furnishes a loss saving of 3 per cent, while the conventional method indicates 10 per cent or more reduction in losses, depending on the flux density in the legs.

In the 3-phase example, Figure 14, the calculation has been checked by an experiment. For this purpose, the originally high yokes of a small 3-phase core of rectangular iron section were reduced step by step and the losses measured before and after each cutting operation. These test values of ΔL change very little with the flux density in the legs, and agree quite closely with those derived from the field distribution. This time a yoke increase of $\Delta\lambda = 40$ per cent with $\Delta G = 16$ per cent, effects an actual decrease in losses of 6 per cent, as compared with 9 to 15 per cent obtained in the conventional way.

From the first example, conclude that the actual losses are, for $\lambda = 1$, considerably smaller than the result of present methods. According to Figures 13 and 14, this discrepancy will decrease if λ is raised; that is, a widening of the yokes reduces the error inherent in conventional calculations.

Conclusions

By the use of loss formulas, derived from the actual field distribution, the designer is able to make a reliable investigation of the economy of any core construction. Not only can the shape of the core be chosen to obtain optimum performance with a minimum cost, but it also will be possible to detect additional stray losses so that they can be reduced. The equations may further form the basis of an analytical design of a new line of transformers.

Appendix I. The Calculation of the Field Distribution

For the calculation of the field in the core Figure 6, the corner region at $O_1\,O_2$ is approximated by an L shaped space A in which the other corners at $O_3\,O_4$, $O_4\,O_5$, and $O_6\,O_7$ are moved to infinity. As shown in Figure 15, this space A represents a polygon $O_1\,O_2\,O_3\,O_4$ which lies in a Z plane ($Z = x + jy$; $j = \sqrt{-1}$). This polygon A is mapped conformally upon a strip A of the width π in a χ plane ($\chi = \varphi + j\psi$) where the distribution of the potential φ and of the flux ψ becomes a simple parallel field. This transformation is made in two steps by referring both regions A to an upper half W plane ($W = u + jv$) so that the iron boundary in the Z plane corresponds to the real u axis in the W plane and to the strip boundary in the x plane.

Since any three points can be co-ordinated freely on these boundaries, choose

Point	Plane Z	Plane W	Plane X
O_1	0	$+1$	0
O_2	$-j\infty$	∞	$+\infty$
O_3	$a + jd$	$-p$	$-m + jx$
O_4	$-\infty$	0	$-\infty$

where p and m represent constants to be determined.

The W and χ planes are mapped upon each other by the function[6]

$$W = \epsilon^{\chi} \quad (\epsilon = 2.7183) \tag{49}$$

According to Schwarz and Christoffel, the polygon transformation from the Z plane upon the upper half W plane is performed uniquely by a function whose derivative represents the given difference of directions of the two boundaries, and is, therefore, subjected to the prescribed changes at the vertices. In order to obtain a general form of this derivative, introduce

γ_1 to γ_4 = the supplements of the polygon angles at O_1 to O_4 in the Z plane
u_1 to u_4 = the co-ordinates of O_1 to O_4 in the W plane
C = an unknown constant

and write

$$\frac{dZ}{dW} = \frac{C}{(W-u_1)^{\gamma_1/\pi}(W-u_2)^{\gamma_2/\pi} \times (W-u_3)^{\gamma_3/\pi}(W-u_4)^{\gamma_4/\pi}} \tag{50}$$

In the special case, Figure 15, that is, for $\gamma_1 = -\pi/2$, $\gamma_2 = \gamma_4 = +\pi$, $\gamma_3 = +\pi/2$, and for $u_1 = +1$, $u_2 = \infty$; $u_3 = -p$; $u_4 = 0$, the factor containing u_2 disappears because of $u_2 = \infty$. Consequently find

$$\frac{dZ}{dW} = \frac{C}{W}\sqrt{\frac{W-1}{W+p}} \tag{51}$$

For computing C and p, develop this expression in the neighborhood of O_2 and O_4, where it will go over into the transformation of a strip region in the Z plane upon the upper half W plane, that is, the function becomes here identical with equation 49 for the mapping of the χ plane upon the W plane, with the exception of the strip width and of the direction of the boundaries. Consequently, write

At O_2; that is, $W \to \infty$;
$Z = C \log W = -j(a/\pi) \log W$

At O_4; that is, $W \to 0$;

$$Z = C\frac{j}{\sqrt{p}} \log W = (d/\pi) \log W$$

introduce the co-ordinates of O_3 into equation 49, and find

$$C = -j(a/\pi); \quad p = (a/d)^2 = (1/\lambda)^2$$
$$m = 2 \log \lambda \tag{52}$$

so that the equation 51 furnishes

$$Z = -j(a/\pi)\int_{+1}^{W} \frac{dW}{W}\sqrt{\frac{W-1}{W+(1/\lambda)^2}} \tag{53}$$

Figure 15. The transformation of a single corner region

Figure 16. The transformation of an upper core region with infinite yoke height

$(\lambda = d/a = \infty)$

Substitute equation 49 into the solution of this integral, and obtain

$$Z = -j\frac{2}{\pi}\left\{a \tanh^{-1}\sqrt{\frac{\epsilon^x-1}{\epsilon^x+(1/\lambda)^2}} - d \tanh^{-1}\left[\frac{1}{\lambda}\sqrt{\frac{\epsilon^x-1}{\epsilon^x+(1/\lambda)^2}}\right]\right\} \quad (54)$$

For the separation into real and imaginary components, combine

$$re^{j\delta} = \sqrt{\frac{\epsilon^x-1}{\epsilon^x+(1/\lambda)^2}}$$

find

$$\left.\begin{aligned} r &= \sqrt{\lambda}\left\{\frac{\cosh\varphi - \cos\psi}{\cosh(\varphi+m)+\cos\psi}\right\}^{1/4} \\ \delta &= \frac{1}{2}\left\{\tan^{-1}\frac{\sin\psi}{\cos\psi - \epsilon^{-\varphi}} - \tan^{-1}\frac{\sin\psi}{\cos\psi + \epsilon^{-(\varphi+m)}}\right\} \end{aligned}\right\} \quad (55)$$

and derive

$$\left.\begin{aligned} x &= \frac{1}{\pi}\left\{a \tan^{-1}\frac{2r\sin\delta}{1-r^2} - d \tanh^{-1}\frac{2(r/\lambda)\sin\delta}{1+(r/\lambda)^2}\right\} \\ y &= \frac{1}{\pi}\left\{d \tan^{-1}\frac{2(r/\lambda)\cos\delta}{1-(r/\lambda)^2} - a \tanh^{-1}\frac{2r\cos\delta}{1+r^2}\right\} \end{aligned}\right\} \quad (56)$$

as basis of the field distribution Figure 1, and of the α field, Figure 12.

The flux density in the core, Figure 6, becomes infinite at O_4 and zero at O_5. If now O_4 and O_5 are moved into the infinity while M and N are retained at $x = -c/2$, the density and the potential will be raised at M, but lowered at N, so that somewhere on MN the potential must remain the same. Approximate the location of such a point by the intersection of MN with the center flux line $\psi = \pi/2$, and introduce the corresponding values of r and δ, derived from equation 55,

$$\left.\begin{aligned} r &= \sqrt{\lambda}\left\{\frac{\cosh\varphi}{\cosh(\varphi+m)}\right\}^{1/4} \\ \delta &= \frac{1}{2}\left\{\pi - \tan^{-1}(\epsilon^{\varphi}) - \tan^{-1}(\lambda^2\epsilon^{\varphi})\right\} \end{aligned}\right\} \quad (57)$$

for $\psi = \pi/2$ into equation 56 to obtain the co-ordinates x and y of the curves, Figure 7, and the scales of

$$\varphi_2 = \varphi(y = -ja) - \varphi(x = -c/2)$$

For checking the accuracy of this approximation, analyze also two models of the whole top half of a core in which the corners at O_5O_7 and O_7O_8 are moved to infinity. In the first case, Figure 16, make $\lambda = \infty$, and choose $c = 0$ for the second form, Figure 17.

In Figure 16, analyze, for reasons of symmetry, only the right half of the core, that is, the region A which becomes a polygon $O_1O_2O_3N$ in a Z plane. By way of an upper half W plane, this polygon is mapped on the right half strip region A in a χ plane with a parallel field of φ and ψ, by choosing the following location of boundary points:

Point	Plane Z	Plane W	Plane χ
O_1	0	$+q$	$+n$
O_3	$-j\infty$	∞	$+\infty$
O_2	$a+j\infty$	-1	$+j\pi$
N	$-c/2$	$+1$	0

if q and n are unknown constants. Simultaneously, the lower half B of the core in the Z plane becomes the lower W plane and the left half strip of the χ plane.

For the co-ordination between the W and χ planes, write

$$W = \cosh\chi \quad (58)$$

and find the polygon transformation from the Z plane upon the W plane by the principle of Schwarz and Christoffel; that is, introduce $\gamma_1 = -\pi/2$, $\gamma_3 = \gamma_5 = +\pi$, $\gamma_4 = +\pi/2$, and $u_1 = +q$, $u_3 = \infty$, $u_5 = -1$, $u_4 = +1$ into equation 50, and derive

$$\frac{dZ}{dW} = C\frac{1}{W+1}\sqrt{\frac{W-q}{W-1}} \quad (59)$$

For computing C and q, develop this function in the neighborhood of O_3 and O_5 where it will go over into the mapping of a simple strip upon an upper half plane, as described by the equation 49. Consequently, write

At O_3; that is, $W \to \infty$;
$Z = C\log(W+1) = -j(a/\pi)\log(W+1)$

At O_5; that is, $W \to -1$;

$$Z = C\sqrt{\frac{1+q}{2}}\log(W+1) = -j\frac{a+c/2}{\pi}\log(W+1)$$

Figure 17. The transformation of an upper core region with zero opening width

$(c = 0)$

introduce the co-ordinates of O_1 into equation 58, and find

$$\left.\begin{aligned} C &= -j(a/\pi) \\ \cosh n &= q = 2\left(1+\frac{c}{2a}\right)^2 - 1 \end{aligned}\right\} \quad (60)$$

so that equation 59 furnishes

$$Z = -j(a/\pi)\int_{+q}^{W}\frac{dW}{W+1}\sqrt{\frac{W-\cosh n}{W-1}} \quad (61)$$

Substitute equation 58 into the solution of this integral, and derive

$$\left.\begin{aligned} Z &= -j\frac{2a}{\pi}\left\{\tanh^{-1}\sqrt{\frac{\cosh\chi - \cosh n}{\cosh\chi - 1}} - \cosh\frac{n}{2}\tanh^{-1}\left[\frac{1}{\cosh\frac{n}{2}}\sqrt{\frac{\cosh\chi - \cosh n}{\cosh\chi - 1}}\right]\right\} \end{aligned}\right\} \quad (62)$$

For $Z = -ja$ the variable χ becomes equal to the drop φ_2 between N and H, Figure 6, so that

$$\frac{\pi}{2} = \tanh^{-1}\sqrt{\frac{\cosh\varphi_2 - \cosh n}{\cosh\varphi_2 - 1}} - \cosh\frac{n}{2}\tanh^{-1}\left[\frac{1}{\cosh\frac{n}{2}}\sqrt{\frac{\cosh\varphi_2 - \cosh n}{\cosh\varphi_2 - 1}}\right] \quad (63)$$

has to be solved for φ_2. Because of

$$0.988 < \sqrt{\frac{\cosh\varphi_2 - \cosh n}{\cosh\varphi_2 - 1}} < 1.00$$

for $10 > c/a > 0.1$, the root in the second term

Figure 18. Approximate and actual potential drops in the upper core region

1—Plotted against c/a for $\lambda = d/a = \infty$
2—Plotted against $\lambda = d/a$ for $c/a = 0$

of equation 63 can be approximated by unity, and furnishes, together with equation 60,

$$\left.\begin{aligned} Q &= \pi/2 + \cosh\frac{\pi}{2}\operatorname{cnth}^{-1}\left(\cosh\frac{\pi}{2}\right) \\ \varphi_2 &= \cosh^{-1}\left[1 + (\cosh\pi - 1)\cosh^2 Q\right] \\ \cosh\pi &= 1 + \frac{c}{2a} \\ \cosh\pi - 1 &= \frac{c}{a}\left(2 + \frac{c}{2a}\right) \end{aligned}\right\} \quad (64)$$

Figure 19. The Carter coefficient

These value of φ_2 are plotted against c/a in Figure 18, where they are compared with the result of Figure 7.

The second model, Figure 17, can be interpreted as a half strip which is slit between N and infinity in a Z plane. According to a suggestion of F. Roeding, the field of this strip is transformed into the parallel flux distribution of a simple strip in an χ plane by using a lower half slit W plane as parameter with the following co-ordination of boundary points:

Point	Plane Z	Plane W	Plane χ
N	0	$-js$	0
O_2	$-j\infty$	$-j\infty$	$+\infty$
O_1	$a+jd$	$+1$	$g+j\pi$
M	$+jd$	0	$+j\pi$
O_3	$-a+jd$	-1	$-g+j\pi$
O_4	$-j\infty$	$-j\infty$	$-\infty$

where g and s are unknown constants.

As can be recognized directly, this transformation is described by

$$\left.\begin{aligned} W &= \sin\left[\frac{\pi}{2a}(Z-d)\right] \\ W &= -js\cosh\frac{\chi}{2} \end{aligned}\right\} \quad (65)$$

These functions may also be derived from the principle of Schwarz and Christoffel,[4–11] if the regions A and B in the three planes are interpreted as polygons. By substituting the co-ordinates of N, obtain

$$\left.\begin{aligned} s &= \sinh(\lambda\pi/2) \\ g &= 2\sin^{-1}\left[\frac{1}{\sinh(\lambda\pi/2)}\right] \end{aligned}\right\} \quad (66)$$

and

$$\cosh\frac{\chi}{2} = j\frac{\sin\left[\frac{\pi}{2a}(Z-jd)\right]}{\sinh(\lambda\pi/2)} \quad (67)$$

Because of $\chi = \varphi_2$ for $Z = -ja$, derive

$$\varphi_2 = 2\cosh^{-1}\left[\frac{\sinh[(1+\lambda)\pi/2]}{\sinh(\lambda\pi/2)}\right] \quad (68)$$

which is plotted against λ in Figure 18, as compared with the result of Figure 7.

Appendix II. The Field Distribution in a 3-Phase Core

For each moment t, the distribution of the fluxes ϕ_1, ϕ_2, ϕ_3 in a 3-phase core type core, Figure 11, can be linearly composed of two single-phase excitations, displaced by 90 electrical degrees and named the α and β fields.[2,11] The peak values B_α of the flux density in the α field are identical with the momentary 3-phase values B_t at the instance when ϕ_1 in the center leg reaches its maximum. The corresponding peak values B_β of the β field are given by the distribution of B_t at the time when ϕ_1 becomes zero. At a frequency f and for $\omega = 2\pi f$, obtain, therefore,

$$B_t = B_\alpha\cos\omega t + B_\beta\sin\omega t \quad (69)$$

in every core point.

The two components of B_t have the same geometrical direction in the areas I, II, and III, Figure 11, so that the peak value B of B_t becomes here

$$B^2 = B_\alpha^2 + B_\beta^2 \quad (70)$$

In the special case $\theta = 2$, substitute the corresponding specific losses w, w_α, and w_β, according to equation 2, find

$$w = w_\alpha + w_\beta \quad (71)$$

and obtain the same equation for the total losses. Consequently, the total 3-phase losses of (I), (II), and (III) could be described by the sum of the single-phase potentials in the α and β fields. Instead of this, derive these 3-phase losses directly from the resultant field since it has in those three areas the same shape and pulsating character as in a single phase core.

In the regions Δ, Figure 11, however, the two components of B_t have different directions, and are to be added as geometrical vectors in equation 69. The resultant vector B_t is moving on an ellipse,[2,5] and represents, therefore, a rotating magnetization. According to test results,[2,5] the corresponding losses are approximately the same as in a pulsating field, and become for $\theta = 2$ the sum of the losses in the α and β fields, as in the rest of the core.

The distribution of the α and β fields in Δ is shown in Figure 12.[2,5] Consequently, the α field is identical with the field above the center leg of a single-phase shell-type core, Figure 10; that is, the corresponding drop φ_u in each Δ becomes the corner drop for a flux $\psi = \pi/2$ in a core type core, Figure 6, and is given by

$$\varphi_u = (1/2)\varphi_c \quad (72)$$

if φ_c is referred to $\psi = \pi$.

The β field has in Δ the same shape as the magnetic field in the gap between a slotted and smooth surface of a dynamo machine with a gap length d and a slot width a. Each slot is causing a loss of σa in flux carrying circumference of the rotor. The coefficient

$$\sigma = \frac{2}{\pi}\left\{\cot^{-1}(2\lambda) - 2\lambda\log\sqrt{1+\left(\frac{1}{2\lambda}\right)^2}\right\} \quad (73)$$

has been found by F. W. Carter,[7,12,13] and is plotted against $\lambda = d/a$ in Figure 19 where it also is approximated by the hyperbola

$$\sigma \cong 0.15/\lambda \quad (74)$$

The potential drop φ_β in each Δ space, Figure 11, corresponds to the gap flux above a slot, and is reduced in the same scale. Consequently, find

$$\varphi_\beta = (1-\sigma)\varphi_u \quad (75)$$

where φ_u represents the drop over a length a in a uniform β field of the yoke.

Discussion

T. D. Gordy (General Electric Company, Pittsfield, Mass.): The author has attacked the problem of calculating core loss in transformers by mathematically determining the flux distribution in the core, obtaining effective core-loss producing weight, then obtaining total core loss from effective weight and specific core loss. This is a mathematical physics approach based upon assumptions that make the problem mathematically solvable.

Hot-rolled sheet steels that have been used in transformer cores for many years do not have variable permeability and pronounced directional effects to the degree that modern cold-rolled highly oriented steels have, and, possibly, by assuming constant permeability and no directional effects, the proposed method of calculation would be justified for hot-rolled sheet steel. However, cold-rolled strip steels have permeabilities that are not only functions of flux density, but also functions of the direction in which flux passes through the strip with respect to its rolling direction. Figure 1 of this discussion shows these variations for a cold-rolled steel used in transformer cores for with-rolling direction, 55 degrees from with-rolling direction, and across rolling direction. These curves do not appear to justify the assumption of constant permeability.

Specific core loss is the loss in the center of the leg section when the lines of flux are uniformly distributed and parallel to the rolling direction. However, in the core, and particularly in the corner sections, flux passes through the core steel at directions other than with the rolling direction. Core loss varies considerably with the direction of flux passing through the steel as well as with flux density. Figure 2 shows these variations for a representative cold-rolled strip steel used in transformer cores.

Considering the effect of variable permeability and directional effects, it is questionable whether or not the analysis presented would yield more accurate results than older methods of core loss calculation. If, however, the author's analysis be modified to account for variable permeability and directional effects, calculated flux distributions and core losses may be verified by tests. These modifications result in introducing harmonics in the flux, especially in corner regions, which in turn affect core loss. The concept of an effective core loss producing weight still may be applied with the modifications mentioned.

Stein's analysis does not account for the effects of joints on flux distribution, core loss, and exciting current. It has been determined that the type of joint affects the flux distribution in the core, total core loss, and exciting current. Figure 3 illustrates the variations of core loss and exciting current with flux density for two types of joints in transformer cores built of modern core steel.

The analysis presented by Stein is a good example of the application of mathematical physics to a rather complex engineering problem with certain simplifying assumptions, and it serves as a guide in the treatment of the problem. However, the method as presented in the paper is not sufficiently complete to be applicable to actual core designs utilizing modern core steels because of variable permeability, directional effects, and joint effects.

G. M. Stein: Gordy proposes to extend the analysis of the paper to the application of cold-rolled steel and to the losses caused by the joints.

It is true that the formulas derived apply only to hot-rolled steel. Cold-rolled material introduces an additional variable since its permeability and losses possess a higher sensitivity to the angle between the field and the grain orientation. As function of the flux density, however, the permeability curve of cold-rolled steel has in Figure 4 of this discussion about the same shape as the curve of hot-rolled steel. The difference in slope at the higher flux densities beyond the point of maximum permeability does not appear large enough to have a profound effect on the flux distribution. In addition to this, the variation of the permeability of cold-rolled steel with the grain orientation is, according to Figure 1 of Gordy's discussion, not worse than the change with the flux density. Consequently, it should be permissible to calculate the flux distribution in cold-rolled steel, like in hot-rolled steel, on the assumption of a constant permeability

The influence of the grain orientation, however, cannot be neglected in an analysis of the core losses for cold-rolled material, but on the basis of a constant permeability the loss formulas may be corrected for this property, as demonstrated hereinafter, since the angles between the flux density and the grain can be derived from the field equations.

A joint may have a 2-way effect upon the losses. First, consider the losses in the joint

Figure 1 (left). Variation of permeability with flux density for a modernt ransformer core steel

Figure 2. Variation of core loss with angle from rolling direction for a modern transformer core steel

Figure 3. Variation of core loss and exciting current with flux density for two types of joints in transformer cores built of modern core steel

A (left). Flux density versus core loss

B. Flux density versus exciting current

itself which are caused by the passage of the flux from one lamination to another. These joint losses are practically independent of the location of the joints in the core, that is, they represent additional losses[1] which lie outside the scope of the paper. In cold-rolled steel also the location of the joints will have an influence upon the losses since the angles between field and grain depend on this location.

In order to illustrate the method by which the losses in cold-rolled steel can be computed on the basis of the flux distribution, consider the example of a core-type transformer with a yoke widening factor $\lambda=1$, whose corner field is shown in Figure 1 of the paper. Let B_x and B_y represent the components of a resultant flux density B_r in each core point and in the x, y, co-ordinate system, Figure 6 of the paper. B_r becomes equal to B in the uniformly magnetized leg center. Then derive from the field function $X=\varphi+i\psi$ of the potential φ and flux ψ by equations 49, 51, and 52 of the paper

$$\left.\begin{aligned} B_x-jB_y &= -\frac{a}{\pi}B\frac{dx}{dZ}=jB\sqrt{\frac{e^X+1/\lambda^2}{e^X-1}} \\ B_x &= \frac{B}{r}\sin\delta \\ B_y &= -\frac{B}{r}\cos\delta \\ B_r &= \frac{B}{r} \end{aligned}\right\} \quad (1)$$

where r and δ are given by equation 55. Note $\varphi=0$ at the corner point O_1. The components b_xB_x/B_r and $B_y=B_y/B_r$ already have been derived as functions of φ in a paper of Stein and Uhlmann[3] in which they appear as Figure 24 for the example $\lambda=1$. The corresponding values of B/B_r are plotted in Figure 5 of this discussion.

For computing the influence of the grain orientation, use the conditions on the center flux line $\psi=\pi/2$ as average for the whole core, where B_r assumes for $\lambda=1$ the constant value B. If the material is magnetized in parallel with the grain in the leg center and if the core consists of full frame punchings without any joints, the quantity δ, given in equation 55 of the paper, will represent the angle between the direction of the field and the grain, and is, therefore, plotted against φ for $\psi=\pi/2$ and $\lambda=1$ in Figure 6. The losses of cold-rolled steel are obtained as functions of δ from test results, so that their rise over the straight grain losses ($\delta=0$) can be added in Figure 6 also as function of φ.

Without considering the grain orientation, the core loss length l^v is given as

$$l^v=(a/\pi)\varphi$$

(equation 18 of paper). This formula also may be written

$$l^v=(a/\pi)\int d\varphi \quad (2)$$

where the integration over φ can be made on the center flux line, and where the differential $d\varphi$ is a measure for the losses in each cross section of the core. Under the influence of the grain orientation, this differential is increased by a factor $1+\tau$ in which τ as a function of φ is given by the iron loss rise, shown in Figure 6; that is, write instead of equation 2

$$l^v=(a/\pi)\int(1+\tau)d\varphi=(a/\pi)(\varphi+\int\tau d\varphi) \quad (3)$$

The integral

$$\varphi_a=\int\tau d\varphi \quad (4)$$

is proportional to the area between the loss curve Figure 6, the abscissa, and the joints wherever they are located, and therefore, will be a measure for the total loss increase caused in each quarter core by the influence of the grain orientation. Such a quantity

Figure 4 (above). Permeability curves of hot-rolled and cold-rolled steel

Figure 5. Distribution of the resultant flux density in a single corner without yoke widening

($\lambda=1$)

Figure 6 (right). The angles between field and grain and the losses of cold-rolled steel at the center flux line of a single corner without yoke widening

($\lambda=1$)

φ_a can be derived in the same way also for all other values of λ, and is practically independent of the length of legs and yokes. Add φ_a to the total core potential given in equation 26 of the paper, and obtain a potential

$$(1/4)\varphi = \frac{\pi b}{2a} + \frac{\pi c}{2a} + 1.44 + 0.25\lambda + \varphi_a \qquad (5)$$

which includes the influence of the grain orientation. Herewith derive in the same way as in equation 38 of the paper

$$\left.\begin{aligned} l'' &= 2[b + (\lambda)^{1-\theta} c + k'' a] \\ k'' &= 0.92 + 0.16\lambda + \frac{2}{\pi}\varphi_a \end{aligned}\right\} \qquad (6)$$

for the single-phase core-type core of cold-rolled steel. The core losses computed by this equation have been found to agree well with test results for which a core-type core has been assembled out of Epstein samples.

Some Economic Aspects of Radio-Frequency Heating

LAWRENCE M. DURYEE
MEMBER AIEE

THE IMPORTANCE of the industrial and commercial field of high frequency heating is illustrated by the following proposed statement of the working group on definitions of the AIEE subcommittee on electronic heating:

Since the installed capacity of these equipments is approaching half a million kilowatts with a total value of between 40 and 50 million dollars, and inasmuch as the volume of business has doubled in each 4-year period since the inception of this type of heating 30 years ago, and since the annual business at present is between 6 and 8 million dollars a year, the importance of this development cannot be overemphasized.

For several years, those in the industry have stressed, in the technical press, the many advantages accruing to users of high frequency heating, together with the technical problems involved. The time now has arrived when these advantages and technical problems must be approached from an economic angle, clarified, authenticated, and simplified by actual analysis and cost data in specific industries. This goal, combined with a study of other important aspects of the subject of high frequency heating, is the purpose of this paper.

Definition of Frequencies

The terms now used to define the general bands of frequencies are in need of revision, due to recent rapid developments. The term "high frequency" in 1925 applied to the 500-cycle coreless-type melting furnaces. Five years ago this same term applied to the 500-kc band used for induction heating. Then followed the vague term "ultra high frequency" employed to describe the band up to and including 30 megacycles in the dielectric field of heating. Now we have developed "microwave heating" in the 3,000-megacycle band. And tomorrow?

So confused have these terms become in this entire area that provision should now be made for fitting all the frequencies of the electromagnetic spectrum into an orderly sequence. This solution, recently discussed and tentatively adopted by the subcommittee on electronic heating, is submitted in Table I.

This proposal is included here simply because any economic study of a problem obviously must have its very beginning in an economy of words and in simplification of terms.

Economics of Generator or Oscillator Selection—Induction

If a generator (or oscillator) feeds a receiving circuit containing both resistance R and inductive reactance X_L, the source must have sufficient kilovolt-ampere capacity, of course, to supply both the power component (kilowatt) and the reactive component (kilovar) of the load. If the reactive component is supplied by shunt capacitors (X_C) then the generator kilovolt-ampere and kilowatt ratings are the same.

Figure 1. Circuit containing resistance and inductance in series, with shunt capacitor

Assuming the cost of the generator, in this latter case, is proportional to its kilovolt-ampere rating, then its cost also will be proportional to its kilowatt power output. This can be written

$$\text{Generator cost (\$)} = AW \qquad (1)$$

where A is a constant and W is power output in kilowatts.

Where we have a circuit, and a load, connected as in the diagram of Figure 1, it is obvious that the capacitor rating in kilovolt-ampere needed to raise the load power factor to 100 per cent is given by

$$\text{Kva (capacitor)} = \frac{W\sqrt{1-PF^2}}{PF} \qquad (2)$$

This is derived from $\tan\theta = \sin\theta/\cos\theta$, $\sin = \sqrt{1-\cos^2\theta}$, and therefore

$$\tan\theta = \frac{\sqrt{1-\cos^2\theta}}{\cos\theta}$$

where W in equation 2 is power in kilowatts delivered to the load, and PF the load power factor.

Since the cost of capacitors is in general proportional to their kilovolt-ampere ratings for given voltages, we therefore may write the following expression for capacitor cost:

$$\text{Capacitor cost (\$)} = \frac{WC\sqrt{1-(PF)^2}}{PF} \qquad (3)$$

where C is capacitor cost, dollars per kilovolt-ampere.

The total cost of equipment for supplying power W to the given load is the sum of both the generator (or oscillator) cost and the capacitor cost. This total cost can be expressed as follows:

$$\text{Total cost (\$)} = \frac{W(A + C\sqrt{1-(PF)^2}}{PF} \qquad (4)$$

where C is again capacitor cost, dollars

Paper 48-17, recommended by the AIEE electric heating committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26-30, 1948 and at the AIEE North Eastern District meeting, New Haven, Conn., April 28-30, 1948. Manuscript submitted November 10, 1947; made available for printing December 16, 1947.

LAWRENCE M. DURYEE is industrial power engineer with the Connecticut Light and Power Company, Waterbury, Conn.

Acknowledgment is given to E. C. Northrup of Trenton, N. J., for his report on fundamentals.

Figure 2. A 9,600-cycle induction heating installation for preheating bolts for hot heading

Figure 3. A 450-kc oscillator and work coil used in instrument manufacture

per kilovolt-ampere, and A is generator cost, dollars per kilovolt-ampere.

As an example, on a 360-cycle frequency changer rated at 250 kilovolt-ampere the total cost of the generator plus a 500-kilovolt-ampere synchronous motor (oversize for plant power factor correction) is about \$7,000 or approximately \$28.00 per kilovolt-ampere of output. This, at 100 per cent power factor load, is \$28.00 per kilowatt. One may take the cost of capacitors at 850 volts and 360 cycles as \$7.00 per kilovolt-ampere, for example. In this particular instance the uncorrected power factor of the load was measured and found to be 0.4. Then, using equation 4,

$A = \$28.00 \qquad C = \$7.00$

$PF = 0.4 \qquad (PF)^2 = 0.16$

Then

$$\text{Total cost} = \frac{W(28.00 + 7.00\sqrt{1-0.16})}{0.4} = \$42.30W$$

If this machine is operated at full load of 250 kilowatt, the total cost is $\$42.30 \times 250 = \$10{,}500$.

If the capacitor constant C is less than the generator constant A it will be cheaper to supply only the power component of the load with a generator of that size, and purchase capacitors for the entire reactive component. If the contrary is true, then the generator (or oscillator) should be of a size to supply the total power and reactive components, leaving the load circuit power factor uncorrected. The foregoing applies to the load circuit in its entirety.

Table I. Band Numbers

Band Number	Frequency	
0	0–10	Cycles per second
1	10–100	
2	100–1,000	
3	1,000–10,000	
4	10,000–100,000	
5	0.1–1	Megacycles per second
6	1–10	
7	10–100	
8	100–1,000	
9	1,000–10,000	
10	10,000–100,000	

Economics of Frequency Selection and Coupling Methods

Theory shows that when the ohmic resistance R measured circumferentially around a pipe, or thin-wall cylinder, which is to be heated above the Curie point is numerically equal to the inductive reactance of the same path then the electrical efficiency is maximum, assuming the resistance of the water-cooled inductor to be zero. This is proved by the following.

Maximum power delivered to the work would result if no reactance were present. This, of course, is not possible, in induction heating. All power is expressed by

$$P = I^2R \tag{5}$$

where I is current and R is resistance. But

$$I = E/Z \tag{6}$$

where E is applied voltage and Z is impedance and

$$P = \frac{E^2R}{Z^2} \tag{7}$$

and

$$Z^2 = R^2 + X_L^2 \tag{8}$$

Therefore

$$P = \frac{E^2R}{R^2 + X_L^2} \tag{9}$$

For any given frequency, maximum power is delivered when $R = X_L$. Hence a frequency is chosen such that

$$R = 2\pi fL \tag{10}$$

where L is self-inductance of the load cross section of the work being heated. This means that the optimum load power factor is 70 per cent.

The formula for load-circuit power factor for a thin-wall cylinder is, by experience and empirical test

$$PF = \cos\theta = \frac{\phi^2 R X_L}{\sqrt{(R^2 + X_L^2)[X_L^2(\phi^4 - 2\phi^2) + R^2 + X_K^2]}} \tag{11}$$

where

ϕ = coupling factor $= d^2/D^2$

where d is mean diameter of cylinder and D is inside diameter of the inductor coil.

Selecting a frequency such that $R = X_L$ then equation 11 becomes

$$PF = \cos\theta = \frac{0.707\phi^2}{\sqrt{\phi^4 - 2\phi^2 + 2}} \tag{12}$$

Varying the coupling ϕ by steps from 1 to 0.5 and substituting these ratios of diameters in equation 12 we get Table II.

These data and table show the rapidity of decrease in the load-circuit power factor as the coupling factor $\phi = d^2/D^2$ be-

Table II

ϕ	ϕ^2	ϕ^4	$\cos\theta$
1.0	1.0	1.0	0.707
0.9	0.81	0.66	0.561
0.8	0.64	0.41	0.425
0.7	0.49	0.24	0.309
0.6	0.36	0.13	0.214
0.5	0.25	0.063	0.141

comes less. The need for close fitting of the inductor coil to the load thus is forcefully made apparent, when one is interested primarily in efficiency.

Based upon the fundamental equation 9 a convenient expression has been developed which recognizes that the *internal* power factor of the work to be heated must be 70 per cent (that is, the resistance of the load itself must equal its inductive reactance)

$$f = \frac{P \times 10^9}{\mu r^2} \qquad (13)$$

where

f = frequency, cycles per second
r = radius of the work in inches
P = resistivity in ohms per centimeter cube
μ = permeability

As an example of this fact, a bolt manufacturer who previously headed bolts by the cold-heading process found, from a study of his operations, that substantial labor-saving money and longer die life would result if he hot-headed bolts before forging, by induction heating. Expensive stress-relieving operations also would be eliminated. He selected, therefore, a motor generator type of equipment producing 9,600 cycles per second, based upon the following:

Diameter of bolts = 1 inch
Radius of bolts = 0.5 inch
$\mu = 1$ (since the forging temperature of 1,650 degrees Fahrenheit is well above the Curie point at which steel loses magnetic properties)

The economic frequency for this application then became, from equation 13

$$f = \frac{140 \times 10^{-6} \times 10^9}{0.5^2} = 5{,}600 \text{ cycles per second}$$

The motor-generator set of 9,600 cycles was the nearest commercial unit available, and after installation, it worked out most satisfactorily. The operational data is tabulated in relation to bolts of 0.875 inch diameter (Table III). It is to be noted that a shunt capacitor of 34.25 microfarads was used at inductor coil terminals, to reduce the kilovars to zero. Figure 2 shows this installation.

Table III. Typical Test Data (9,600-Cycle Motor Generator Set)

Specific Case Histories Including Economic Data Induction

Induction heating is defined tentatively by the AIEE subcommittee on electronic heating as "the heating of a nominally conducting material due to its own internal losses when the material is placed in an alternating electromagnetic field."

The following group of case histories of induction heating equipments utilizing vacuum tube oscillators serves to illustrate the economic advantages—or disadvantages—in specific industries. The outstanding development which this survey revealed, and one which is of special interest, lies in the way in which each particular heat-treating engineer in the industry studied, solved his own work-handling and fixture problems. Moreover, the ingenuity of coil design was, in many cases, unusual, and the method by which these coil designs were developed so successfully was, in almost every case, the process of trial and error. General fundamentals were adhered to, of course, such as thin-wall coils for close coupling; multiple-turn coils in place of one turn, where possible, for the nonmagnetic products, to increase I^2R heat absorption; and adequate turn-to-turn insulation where voltages demanded. In general, however, emphasis was placed upon ease of operation by the unskilled worker who performed the daily work, rather than on the objective of realizing the highest coil efficiency. The results, in terms of final product cost, when heated by induction, prove the practicality of this approach.

Table IV is a recapitulation of results obtained on a variety of products at the Bristol Instrument Company, Waterbury, Conn. It is to be noted that total annual savings for brazing and spot annealing the many instrument parts in this plant amounted to approximately $10,000 per year, which retired the investment in the high frequency oscillator in one year. A second induction heating oscillator has been ordered of exactly the same specifications as follows:

Output—15 kw at 450 kc (band 5)

Input—25 kva, 3 phase, 60 cycle. Load power factor of oscillator is 95 per cent at the 60-cycle input side

Remarks. In the case of the damping magnet (item 7 in the table) a high-cost steel alloy formerly was used when brazing was performed by hand. The use of the localized and extremely rapid heat furnished by the induction process enabled the user to substitute a cheaper steel. Further, this steel part is brazed inductively to the Alnico, which possesses a Curie point of ±900 degrees Fahrenheit without damage to the magnetic property of the Alnico. Figure 3 shows the oscillator and work-coil; Figure 4 the various coils used in this plant; and Figure 5 the damping magnet with Alnico brazed to steel.

Table V shows the results at the Cleerman Machine Tool Company, Green Bay, Wis. The oscillator hardens SAE 4150 steel gears, using 15 kilowatts of out-

put energy at 525 kc (band 5). Figure 6 is a view of this installation. The plant saves a total of $1.70 on each gear hardened, and produces a far more accurate gear by reason of reducing distortion to a minimum.

Table VI applies to the tempering of hatchet heads in the plant of the Mitchell and Unsinn Company, Washington, D. C. This plant formerly flame-tempered the heads. With this flame process, one man placed the untempered hatchets on an endless chain. The hatchets then were conveyed down a chimney-like structure at the rate of 8 feet per minute and were thus preheated before they entered the flame. After passing through the flame, the products fell on a series of baffles inside the chimney and from there, they slid down into an oil bath. This produced 650 hatchets per day. Figure 7 illustrates the installation.

When flame-tempering was replaced by induction heating using a 20-kw-output oscillator, only one operator was needed in place of two formerly and the hatchets came out clean, uniformly tempered, and at twice the production rate per day. The induction coil produces 1,300 hatchet heads daily.

Table VII emphasizes the principle demonstrated in Table IV, that induction heating is justified economically not only for large production runs, but also for a wide variety of small-lot requirements. Products in this column are brass parts. Note the simple setups used since expensive fixtures were not justified by the small production runs. Here a nipple on the end of a cable guide is silver soldered. Multiple-turn coils of conventional design enable these and other applications to be done in a fraction of the time formerly required. For example, by using a standard 20-kw 450-kc oscillator, a leading manufacturer of electric equipment has the time study figures to report as typical. Time values shown are from detailed time studies, and they include the complete production cycle of handling, heating, and removal. Figure 8 is a view of one of the operations.

Table VIII illustrates the use of a radio-frequency oscillator applied to continuous production with the use of an indexing turntable to hold the product and to move it automatically into the work coil. The Benrus Watch Company, Waterbury, Conn., formerly brazed nickel-silver watch cases to stainless steel backs by hand, using irons. After several months of experimental work and the ingenious application of induction brazing to the product by their development engineer, a 375-kc oscillator was set up and obstacles successfully overcome. In addition to the annual saving of $7,800 per year, which retires the investment in the first 12 months of use, fewer rejects are experienced with induction brazing. Further, distortion is completely eliminated with the clever fixture designed for this job. In addition, the user is no longer dependent upon skilled labor since unskilled girls now are employed who merely preset the brazing wire and load the machine. Four cases are brazed in each 15-second heating cycle. A gas

atmosphere is bled into the hood which surrounds the work coil of 85 per cent nitrogen and 15 per cent hydrogen to produce a clean product. The machine is rated at 20 kilowatt output and uses a coupling transformer of a turn ratio of 22 to 1 at the work coil. Figure 9 is an illustration of the setup.

Dielectric Heating

Dielectric heating is defined, tentatively, by the working group of the AIEE subcommittee on electronic heating as "the heating of a nominally insulating material due to its own internal losses when the material is placed in a varying electric field."

While frequency selection is not as simple as in the general field of induction heating, there is nevertheless a means for a definite conclusion to be reached based upon the fundamental concept of dielectric heating.

Maximum heating speed is related to frequence as follows:

$$\text{Time } T = \frac{0.43K \times \text{temperature rise} \times S \times D}{f \times C \times PF} \tag{14}$$

where

f = frequency, cycles per second
T = time in seconds
S = specific heat
D = density in pounds per cubic foot
C = dielectric constant
PF = power factor of material between the electrodes (the work to be heated)
K = a constant related to the shape and thickness of the work

and temperature rise is in degrees Fahrenheit.

Thus, the higher the frequency in general, the shorter is the heating time. However, since the limit of frequency is the available and efficient power output from commercially obtainable oscillators, a frequency of approximately 30 megacycles is the approximate top limit for industrial purposes. This frequency recently has been fixed at 27.32 megacycles by the Federal Communications Commission. A still more simplified form of equation 14 is submitted which relates heat absorption to frequency and voltage as follows:

$$H = C \times LF \times F \times V^2 \tag{15}$$

where

H = Btu per second per pound of material being heated
C = constant varying with density and specific heat of the product
LF = loss factor expressed as a decimal (a product of dissipation factor and dielectric constant)
F = frequency in megacycles
V = volts per inch across the piece being heated

From experimental work and practical application, predominantly in the field of preheating plastic preforms in the compression molding industry, we can apply known values in equation 15 as follows, for a typical compound of cellulose-filled vinyl acetate heated at an applied power rate of 1.5 kw per pound, at a voltage gradient of 2,400 volts per inch giving 1,015 Btu per second. Inserting these data and solving for f with varying values of V, the data in Table IX have been prepared. Since 3 kv per inch is the maximum voltage stress possible without arcover, it appears that from 14 to 28 megacycles is the approximate practical frequency range when conventional electrodes are used. In band 9, which to date has had its application in the field of high speed commercial cooking, wave guides are employed and energy is absorbed by the food in a combination of both induction and dielectric heating.

The application of dielectric heating processes to industry, while newer than induction due to the more recent development of power tubes for oscillator circuits in the megacycle band, nevertheless has expanded rapidly. The heating of nonconducting materials by conventional means always has presented a problem due to the critical nature of the surfaces of these products which entailed slow heating by convection, radiation, or conduction. This is due, of course, to limitations of surface temperatures and required long soaking periods for the product to be brought to temperature. This time cycle in the case of nonconducting ma-

terials was lengthened further with conventional heating due to thermal insulating properties of these materials. Therefore, with the advent of megacycle heating from electronic oscillators, industries immediately seized upon the opportunities offered by this new process of internal heating and thereby expanded their production. The case histories presented in the following are typical of production increases made possible by dielectric heating. There are, of course, many materials which possess unsatisfactory heat absorption factors which cannot at this writing be heated economically in radio-frequency fields.

Foundry Application—Dielectric Core Baking; Band 7

In the field of core baking in foundries, the new development of dielectric baking is capturing the interest of foundrymen. At the Lehigh Foundry, Lehigh, Pa., continuous dielectric baking of cores has been in practical operation for several months replacing conventional oven baking. It should be borne in mind that any new process necessitates extensive research which in this case resulted in some substantial changes in foundry practice. Notable among these changes were the substitution of materials (wood) for core supports, improved synthetic resin binders instead of oils, and plastic core driers instead of metal. The following resultant advantages have been reported though it is too early for specific dollar evaluations to be put on these items.

1. Direct labor saving.

(a). Green sand handling reduced.

(b). Mulling of mixtures reduced from 12 minutes to 5 minutes per mix.

(c). Loading of a conveyor from the core benches reduces handling of cores.

(d). Baked core handling reduced due to finished cores being conveyed directly to inspection tables.

(e). Loading and unloading of racks is eliminated.

(f). Finer finish on core surfaces reduces labor of removing metal fins on the castings.

(g). Shake-out labor is reduced due to the core residue becoming merely a fine powder easily removed from the metal cavities.

2. Improvement in collapsibility due to distillation of cores.

3. Increase in yield due to reduction in rejects resulting in decrease of rejects from a former 30 per cent figure to 10 per cent with dielectric baking of cores. Uniform baking accomplished by the dielectric method accounts for this.

4. Negligible "gassing" results from a minimum of volatile content in the resin binder. This reduces turbulence when metal is poured and improves the metal surfaces.

5. Reduction in number of core mixtures due to standardization with dielectric core baking regardless of the shape of the core.

6. Reduction in driers in stock because cores are baked in two minutes instead of two hours.

7. Overbaking eliminated. No matter how long the cores remain in the high frequency field, heat absorption of the cores stops before dangerously high temperatures are reached. This is due to the drop in power factor of the synthetic resin as temperature increases.

8. Fuel consumption is relatively low.

Table IX. Relation Between Kilovolts and Megacycles

Kv Per Inch	Frequency, Megacycles
23.2	0.5
11.6	1.0
6.2	3.5
4.4	7.0
3.1	14.0
2.2	28.0

Heat supplied is proportional to the actual load. Electrodes remain at room temperature and no external heat is lost save in the radio-frequency circuit and radiation of product.

The capacity of this production unit is 500 pounds of cores per hour. The investment is $11,000. The full-load power input is 25 kw. The output is at 15 megacycles. Figure 10 shows the core-baking machine with the operator loading the product onto the moving conveyor. Cores are about to enter the shielded electrode chamber.

Plastic Molding; Band 7

Preheating of plastic preforms at the Bryant Electric Company, Bridgeport, Conn., is illustrated in Figure 11. Preformed "pills" are heated uniformly to a plastic state before being transferred to the compression molding machine. Substantial reductions in total molding time result. In addition, slender pins and inserts can be used in the molds without fear of shearing. Table X lists the results in percentages. A standard oscillator of 5-kw output is used here. On special items such as the heavy-section motor housings for vacuum cleaners, preheating with megacycle energy increased the production 169 per cent per man-hour.

Commercial Cooking; Band 9

Radio-frequency heating has entered the kitchen of hotels and restaurants. The Radarange which has been used successfully by a well-known hotel chain for rapid cooking of uniformly mixed foods now is finding its way into smaller restaurants as well. The range uses the

Figure 13. Radio-frequency-generator operating cost curve

Figure 14. Operating cost factor for fractional generator output

type *QK217* magnetron. It has a maximum power input of 7.6 kva at 70 per cent power factor, 230 volts (to the range) single phase, 60 cycle. The output is 1.7 kw of energy at 3,000 megacycles. A complete meal consisting of breast of chicken or Virginia ham with corn and tomatoes is cooked in 60 seconds. Several additional installations are being made in the hotels of the chain which pioneered in this form of cooking, which indicates the degree of acceptance of this new use of radar frequencies. Proper wave guides direct this energy to the food which is placed in the oven compartment. Figure 12 is a view.

While no direct cost comparisons have been made as yet, a typical small restaurant which serves between 300 and 400 patrons per day utilizes this range for all the cooking and supplements the Radarange by a conventional electric broiler in order to put the familiar broiled surfaces on the food prepared in the radio-frequency range. A combination of both dielectric and induction heating accomplishes the high speed cooking from the extremely high frequencies of band 9.

Radio-Frequency Cost Data—Vacuum Tube Oscillators

In general, the operating cost in dollars per hour for the standard commercially available oscillators may be determined from graphs, Figure 13. Tube cost, amortization cost, and power cost are plotted for the various size oscillators. Total cost for a given application must include, of course, labor and work handling cost as well as the increased fixed cost on work handling investment. The curve of Figure 13 is based upon

1. Current prices for radio-frequency generators (minus accessories).
2. Amortization based upon 30,000 hours of operation.
3. Input power cost at one cent per kilowatt-hour.
4. Oscillator tube life of 5,000 hours.
5. Rectifier tube life of 3,500 hours.

Furthermore, since the curve, Figure 13, is based upon 100 per cent duty factor, the operating cost for other than 100 per cent duty factor can be found from curve, Figure 14. Values found from Figure 13 should be multiplied by the "operating cost factor" from Figure 14 which is an average of the cost factor of standard sizes of oscillators now available. Over-all operating efficiency, including stand-by power, is accounted for in this curve. It is accurate to within 10–15 per cent.

Table X

Material saved	12 per cent
Production increased	25 per cent
Mold life increased	30 per cent
Mold cost decreased	67 per cent
Cure time decreased	91 per cent

Conclusion

High frequency heating is not a cure-all for every industrial or commercial heating problem. Moreover, because of the high investment represented in this type of equipment, the financial hazards in investing in it are obviously greater. If a purchaser of a high-frequency heating tool unexpectedly loses an important contract, for a long production run, of products readily adapted to the machine, the financial burden may be great and the decision to purchase may prove to be unwise. This is due to the fact that the capacity cost for equipment per Btu per unit of time, which these machines represent, is obviously greater than with other comparable heating tools. This entails higher annual fixed costs on the equipment investment. This is especially true of the obsolescence factor (amortization) which in high-frequency heating is obviously greater due to the rapid developments and changes compared to the more conventional heating tools.

Despite these inherent hazards, the use of induction and dielectric heating is expanding rapidly due to advantages inherent in the processes. In induction, the major factor is the localized heating obtainable with extreme speed and control of the depth of heat penetration. In dielectric, the uniform, rapid heating accomplished throughout the mass by "molecular friction" when the product is of uniform loss factor represents a phenomenon not associated with other forms of heating. The case histories herein presented are typical of the operations in this combined field of radio frequency heating and were selected at random from the thousands of installations throughout the country. In specific cases, equipment investments have been retired in as short a time as a few months. From the data presented, however, it is seen that a one or two year retirement is the general trend when high-frequency heating is applied with sound engineering to industrial heating applications.

Electrical Insulation Deterioration Treated as a Chemical Rate Phenomenon

THOMAS W. DAKIN
NONMEMBER AIEE

Synopsis: The basis is presented for a more accurate interpretation of the results of physical type tests to measure the thermal aging of insulation together with a more accurate method of applying the results of such tests to predicting insulation deterioration in practice. Since the observed physical changes during thermal aging are the result of internal chemical changes in organic material, it is shown that the theory of chemical reaction rates can be applied to analyze experimental data on aging. The approximate 7 to 10 rule for the temperature coefficient of deterioration rate is replaced by a more accurate theoretical expression. Various examples of insulation life tests are analyzed using the graphical methods outlined in the paper. The chemical rate theory interpretation of thermal aging offers a more satisfactory method for extrapolating the results of limited aging tests of insulating materials so they can be applied to predicting amounts of thermal aging in high temperature cycles.

THE PURPOSE of this paper is to present a logical method of interpreting the measured changes in physical or electrical properties of insulating materials during thermal aging. This method is based on the assumption that the observed physical changes are the result of internal chemical reactions which obey well established theoretical laws. In place of the commonly used rule referred to in the AIEE Standards number 1 which predicts a decrease in insulation life by one half for each 7 or 10 rise in temperature, this analysis offers a more accurate equation for the temperature coefficient of insulation life or conversely of the rate of deterioration.

The method of analysis to be presented in this paper is intended to give a more accurate means of extrapolating the results of controlled temperature accelerated aging tests, and of applying the results of these tests to predicting the life of insulation in electrical apparatus under conditions the same as in those in the test, but with a varying or cycled temperature.

In illustrating the application of this method of analysis of deterioration rate data, examples of a variety of insulation deterioration tests will be discussed. It is assumed that it is possible to know the specific reason for electrical failure in the form of a short circuit. Often this reason is a mechanical failure in the insulation as a result of the decrease in the tensile strength or flexibility. In other cases the failure is electrical in nature as a result of the decrease in electrical resistance to too low a value or similar effect. This paper will not discuss the problem of selecting the test or condition of the physical property of the insulation which best corresponds to the failure point or imminent failure point in the apparatus. But this paper starts out from the point where such a test has been selected and discusses the use of data from controlled test experiments.

Chemical Processes in Insulation Deterioration

The chemical changes are many fold which may occur in organic insulating materials with time under conditions of elevated temperatures and applied voltage, with or without the presence of an oxidizing atmosphere and numerous catalytic substances including the copper and iron of the apparatus, itself. The most common form of deterioration is slow oxidation which introduces acid groups into the polymeric or liquid insulation, which acid groups increase the conductivity and power factor of the insulation. The oxidation also splits up the polymer chains in resin insulation and decreases the tensile strength.

Another important type of deterioration is the brittle hardening of insulation as the result of loss of plasticizer and excessive oxygen cross-linking of polymer chains in plastic insulation. In the first place, it is merely a slow evaporation of the lower molecular weight substances in the plastic which, when present, renders it flexible. In the latter case, the introduction of oxygen increases the cohesion between some neighboring chains while, at the same time, breaking the chains to make them shorter. This has the net result of increasing the hardness, but decreasing the strength to bending or stretching.

A third type of deterioration is the purely thermal or internally catalyzed depolymerization of plastic insulation. This phenomenon where polymer chains break into shorter units occurs in all polymers including cellulose at elevated temperatures even in the absence of oxygen. This reaction is, in general, a much slower one than oxidation, but at high temperatures it becomes an important factor.

It is not the purpose of this paper to discuss in detail specific chemical reactions which deteriorate insulation. A few types have been mentioned. There are others including electrolytic reactions and spark or corona induced reactions. It is rather the purpose of this paper to discuss subjectively chemical reaction rates as they affect the measurable physical properties of insulation.

Paper 48-19, recommended by the AIEE transformer committee and approved by the technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted November 10, 1947; made available for printing December 17, 1947.

THOMAS W. DAKIN is with the physical section, insulation department, research laboratories, Westinghouse Electric Corporation, East Pittsburgh, Pa.

The author wishes to express appreciation to the various members of the Westinghouse research and engineering staff from whose reports the experimental data used to illustrate this paper was obtained. He wishes to acknowledge particularly the work of L. McCulloch who obtained the data on aging of cellulose. He also wishes to acknowledge the continuous encouragement of C. F. Hill (F'39), manager of the insulation department of the Westinghouse Research Laboratory, in this work.

Figure 2. Decrease in tensile strength of cellulose paper in oil under nitrogen with time of aging at elevated temperatures both plotted for linear scales

Chemical Rates in Insulation Deterioration

Physical chemists have for many years been investigating the rates of many different types of reactions and their conclusions can be applied in a rather simple and general manner to the special problem of electrical insulation deterioration. Their investigations have been concerned with the rate of change of concentration or amount of certain constituents of chemical mixtures or solutions as a function of time and, also, with the variation of this rate of change with temperature. Their method of approach can be applied to the problem of insulation deterioration if we know or can assume that the physical property in which we are interested is proportional to the concentration of an important constituent or is a simple function of the concentration. Expressing this mathematically, we assume that:

$$P \sim C \text{ or } P = f(C) \tag{1}$$

where P is the magnitude of the physical property in which we are interested and C is the concentration of an important chemical constituent of the insulation which is being changed by the thermal aging.

For example, the dependence of tensile strength of paper is probably somewhat more complicated,[1,2] but it has been found to be fairly correct to assume that the tensile strength of paper decreases in proportion to the average number of links in the cellulose, molecule chains. In the process of deterioration, this chain length decreases progressively, the links or interatomic bonds being broken at random places along the chain. The number of links in the cellulose chain are analogous to the concentration of a chemical species, which is being transformed by the reaction.

In general, the instantaneous rate of change of the number of molecules undergoing a transformation with time is proportional to the number present raised by some exponent or, stating this mathematically,

$$\frac{dC}{dt} = -KC^n \tag{2}$$

where C is the variable number per unit volume or concentration, K is a rate constant and n is an exponent which determines the order of the reaction. Usually, but not always, n the number of the same kind of molecules reacting with each other and this is usually 1 and hardly ever more than 3. The rate constant K is dependent on the temperature, the concentration of catalysts and other chemicals entering into the reaction, which in the equation 2 are assumed to be a constant throughout the reaction. A more elaborate treatment would consider the time variation of these other components of the reaction.

Integration of equation 2 in the case of a first order reaction ($n=1$) gives

$$\log_e C = -Kt + \log_e c_0 \tag{3}$$

$$C = c_0 e^{-Kt} \tag{3a}$$

It can be seen from equation 3a that the concentration of a chemical being transformed in a first order reaction decreases exponentially with the time. Unfortunately many processes of deterioration in insulation do not follow a simple first order reaction mechanism, or the change in the concentration of other chemical compounds entering or affecting the reaction must be considered. In general, however, a mathematical function of the concentration of the most important chemical constituent can be found which is an integral of equation 2 regardless of what the order of the reaction is or whether the rate constant varies with the time

$$f_0(C) = -K_e t \tag{4}$$

In equation 4, the rate constant K_e is temperature dependent, but not time dependent. The form of function $f_0(C)$ is assumed to be independent of temperature. In the case of the simplest first order reaction, equation 4 would be the same as equation 3 and our function $f_0(C)$ is simply $\log_e (C)$.

Now by introducing the assumed relation between the physical property and the concentration of the most important chemical constituent given in equation 1, a simple relation between the physical property and the time is obtained:

$$f_0'(P) = -K_e t \tag{4a}$$

A graphical plot of $f_0'(P)$ versus time gives a straight line, and a straight line can be readily extrapolated to predict the condition of the physical property at any later time after the slope is established by a short time test. If the mathematical form of the function $f_0'(P)$ is not known, the function must be established on a graphical scale by measuring and plotting the change in the physical property, P, with time at an elevated temperature where the test can be completed in a reasonable time. An example of this is shown in Figures 4 and 5 to be discussed later.

Chemists have shown that the temperature dependence of a reaction rate very closely follows an exponential law:

$$K_e = Ae^{-B/T} = \text{a reaction rate constant} \tag{5}$$

or

$$\log_e K_e = -\frac{B}{T} + \log A$$

In this expression A and B are constants and T is the absolute temperature. It is important to note that the absolute temperature scale is used, consequently the temperature intervals at high temperatures have, percentagewise, less effect on a reaction than the same temperature intervals at low temperatures. This fact is neglected in the commonly used rule of thumb,[3,4] where the temperature interval for which a reaction rate doubles is used. Such rules may be correct for one temperature, but quite incorrect for a higher or lower temperature. The correlation between the exponential law of equation 5 for some commonly encountered values of the constant B and the temperature interval for which a reaction rate doubles is shown in Figure 1. The theoretical exponential law is recommended as being more accurate, remembering that each reaction may show a different temperature coefficient. Gross errors are likely to be encountered in applying the same temperature coefficient under all conditions.

A combination of equations 4a and 5 gives another useful relation.

$$\frac{f_o'(P)}{t} = K_o = A\epsilon^{-B/T} \qquad (6)$$

If one selects a particular value for the property, P, as, for example, 20 per cent of the original tensile strength as a limiting danger point for paper insulation, it is apparent that $f_o'(P_{20\ \text{per cent}})$ may be considered a constant and the time to reach 20 per cent tensile strength (this might be selected as the life of the insulation) considered as a reaction rate constant and treated as a function of the temperature:

$$\frac{\text{constant}}{t_{20\ \text{per cent}}} = \epsilon^{-B/T} \qquad (7)$$

$$\log_e t_{20\ \text{per cent}} = \frac{B}{T} + \log_e \text{constant} \qquad (7a)$$

Therefore, the logarithm of the time to reach a particular value of tensile strength (20 per cent in this case) is proportional to the reciprocal of the absolute temperature, and a linear graph will furnish a more accurate method of extrapolating high temperature measurements to low temperatures. See Figure 8 for an example of this.

The implication of equations 4a and 6 is that each magnitude of the physical property corresponds to a particular concentration of the significant chemical constituents in the insulation, and that this concentration is the same for the same magnitude of the physical property whether attained at high or low temperatures or by a cycled temperature.

If more than one chemical reaction proceed simultaneously, and if these reactions have different temperature coefficients, a plot of the logarithm of the reaction rate constant or the time to reach a certain state of deterioration against the reciprocal of the absolute temperature may not fall on a straight line. It is however, still preferable to plot the data than to rely on an 8 or 10 degree rule.

Examples of Insulation Deterioration

In all tests of insulation deterioration, there is likely to be found a rather wide dispersion of test results, as a consequence of inadequate control in the preparation of the samples or of inadequate control of the aging conditions such as temperature or atmosphere to which conditions the life or rate of deterioration are very sensitive. Another source of dispersion of test results is in the method of test of the physical property or end point which may throw too much weight on the operator's technique or judgment. For these reasons, it should be emphasized that test results should be interpreted in a statistical manner with sufficient duplicate tests run to obtain a good average, and recognition taken of the statistical probability of deviations from this average in individual cases.

As one example of the method of treatment of deterioration rate data outlined here, some recent experiments on the aging of cellulose insulation will be discussed. The result of these experiments illustrate the type of data which can be obtained, where a physical property is measured as it changes progressively during the period of deterioration.

The AIEE transformer subcommittee group on co-ordination of aging of transformer insulation reported[5] a series of

Figure 3. Decrease in tensile strength of manila paper in oil under nitrogen plotted on a logarithmic scale with time of aging at elevated temperatures plotted on a linear scale

tests showing the decrease in tensile strength of dry paper sealed in oil under nitrogen and aged at elevated temperatures. The data obtained from two of the laboratories which ran the tests are plotted in Figure 2. The slope of the curves of tensile strength versus time indicated a possible first order reaction law dependence as in equation 3 and the plot of the logarithm of the tensile strength versus time in Figure 3 confirmed this by displaying a fair fit to a straight line at each temperature. The spread of the data from the different laboratories indicates the order of reproducibility of this sort of data. Similar data reported[6,7] by F. M. Clark using the same conditions of aging when replotted as in Figure 3 were also found to follow a linear dependence at all temperatures.

The conditions of aging are very important in affecting the deterioration rate. For example, when pressboard and cotton tape are sealed with the paper tape in a test otherwise the same as that just described, the decrease in tensile strength is less rapid and no longer follows a first order chemical reaction rate law. The data from such a series of tests run by L. McCulloch of the Westinghouse laboratory are given in Figure 4. Similar tests had been run for a shorter time by Vogel and Sloat.[8] A scale can be established as implied by equation 4a, however, which transforms the curves of Figure 4 into straight lines, which can then be more easily extrapolated. The tensile strengths of Figure 4 then can be replotted in Figure 5 on this graphical scale. Where no first or second order reaction rate law is obeyed as in this case, it must be surmised that some other chemical whose concentration is changing is affecting the reaction. In other words, the constant K of equations 2 and 3 is no longer a constant or there may be several reactions with different reaction rates proceeding simultaneously to affect the physical property which is being measured.

In this particular case, the water and acidic products of decomposition of the paper tape may be absorbed by the relatively larger amount of pressboard and cloth present. It was found in another test by L. McCulloch that attaching a cold condenser tube to the sealed system had a similar beneficial effect on reducing the rate of decrease of tensile strength of the paper tape.

The time to reach 20 per cent tensile strength of paper under various conditions is plotted as a function of reciprocal absolute temperature in Figure 6. These data show a linear relation on this graph and extrapolation to lower or higher temperatures can be done with greater confidence. The conditions of aging are obviously of great significance, and close comparison of test conditions to actual operating conditions of the insulation in practice should be made, before applying deterioration rate data.

Another example of an insulation deterioration which follows a first order reaction rate law is the arbitrarily designated static life test run by L. E. Frost of the Westinghouse laboratory on insulating varnishes. In this test the varnish coated on a brass rod is aged at elevated temperatures and then periodically immersed in a salt water solution and the resistance between the salt water solution and the rod through the varnish is measured. In such an experiment the resistance of all common organic varnishes decreases logarithmically with the time. In other words, the log of the resistance when plotted against time linearly follows a straight line as in Figure 7. Silicone varnish films tested in this manner show, as a result of the initial period of curing of the resin, an increase in resistance. After this period of curing is over, the resistance here also decreases logarithmically with time, but at a much lower rate than with common varnishes. In this type of test, the point where the resistance has decreased to 1 per cent of the original value is arbitrarily selected as an end point.

Analysis of the rate of weight loss of organic varnish films shows that no simple reaction rate law is followed. This might be expected considering the probable simultaneous occurrence of several different reactions: oxidation and evaporation and depolymerization, all of which may contribute to the weight loss. However, it has been found that a graphical function similar to that of Figure 5 can be

established to describe the weight loss variation with time. If the weight loss data are plotted on this graphical scale against the time, the data at all temperatures fall on straight lines which permit easy extrapolation.

In many tests of insulating materials, only a failure point is measured, and there is no graph of the gradual decrease of a physical property. Nevertheless, according to the interpretation of equation 6, the time to reach this failure point is reciprocally proportional to the rate at which this point is reached. Therefore, the reciprocal of the time to reach the failure point can be considered as a reaction rate constant, and the failure point corresponds to a particular state of chemical composition, this state being the same regardless of the rate at which it was reached. In Figure 8 are plotted on one graph the results of several types of insulation deterioration tests. The common ordinate is the day's time to reach the arbitrary failure point. In the case of the d-c capacitor lives shown by curves *a* and *b*, this failure point is truly the life of the insulation to short circuit. In this case, electrochemical action is probably a contributing factor.

The abscissa scale of Figure 8 is the reciprocal absolute temperature, which is the proper scale to use, but the corresponding centigrade temperatures are given for convenience.

If the particular state of deterioration which is measured always corresponds to a particular extent of chemical reaction in the insulation, it is not essential to know just what the chemical reaction was which resulted in the deterioration to apply this treatment of the data. A curved line on such a plot as Figure 8 indicates more than one reaction is taking place, the respective reactions having different temperature coefficients.

Integration of Deterioration over a Variable Temperature Load Cycle

If the electrical apparatus is subject to intermittent loading with temperatures of the insulation during the overload cycle exceeding those normally encountered, the data given in this paper or data similar to it may be readily used to compute the deterioration during the excessive temperature period. Let us assume that the temperature of the insulation during the overload cycle has been determined, and that the temperature variation with time is that given in Figure 9a with the normal, continuous operating temperature at 90 degrees centigrade at the hottest spot. At this temperature the expected life of the paper insulation to reach 20 per cent tensile strength would be about 76 years, under the conditions of the test when fullerboard and cloth are included with the paper in a nitrogen filled transformer. Excessive temperatures exceeding 90 degrees centigrade for tempo-

FIG. 9b

rary periods would shorten this.[9–12]

The first step in computing the effect of an overload cycle is to find the relative average rate of deterioration for the period of the cycle. This is easily done once the temperature-time curve is known Figure 9*a* and the life-temperature variation Figure 6 is obtained. From equation 6 it is seen that the rate of deterioration is inversely proportional to the time necessary to reach a particular condition of deterioration (the same for all temperatures). Therefore, to obtain the relative rate of deterioration at different temperatures, we merely take the reciprocal of the times to reach 20 per cent tensile strength, or whatever other end point is selected. These time values are taken from the upper line of Figure 6 and plotted corresponding to the temperature of Figure 9*a* to give a relative rate of deterioration curve of Figure 9*b* for the overload cycle. The average relative rate of deterioration for the overload cycle is readily obtained by integrating the area under curve 9*b* and dividing by the total time of the cycle. The average relative rate of deterioration for the sample overload cycle shown in Figure 9*a* is 76.2/1.415 = 53.8 times what it would have been at the normal temperature of 90 degrees centigrade. Therefore, this single cycle of 12 hours has subtracted 53.8 × 12 hours = 26.9 days from the life of the insulation (76 years).

If the duty of the transformer consists of a continued series of equal overload cycles with no temperature that can be considered normal, it is better to find the effective average temperature for the cycle and then simply consider that the transformer is operating continuously at that temperature. If, for example, the transformer operated repeatedly over a cycle of temperature like that of Figure 9*a*, the effective average temperature would be found in Figure 6 corresponding to the reciprocal of the relative average rate of deterioration $1/1.415$ years^{-1}, and the effective average temperature is 125 degrees. Under a condition of repeated operation over this temperature cycle, it would take 1.415 years for the tensile strength of the insulation to reach 20 per cent of its original value.

Summary

In this paper it is assumed that it is possible to select a physical condition of the insulation (an end point) which is considered hazardous to the operation of the electrical apparatus. It has been shown how, using generalized chemical reaction rate laws, it is possible to quantitatively describe the deterioration of the insulation to this selected end point. Use of the graphing methods outlined in this paper permits extrapolation of the results of short time experiments to longer periods of time and other temperatures with more confidence. The theory outlined here has been applied to experimental data on cellulose paper deterioration and other types of insulation deterioration tests. It is emphasized that close attention should be given to insuring that laboratory test conditions correspond closely to all conditions in actual electrical apparatus if such tests are to be used in predicting the life of insulation in the apparatus; also, a sufficient number of duplicate tests should be run to obtain a good average and information concerning the statistical variation from this average obtained.

Discussion

V. M. Montsinger (General Electric Company, Pittsfield, Mass.): The author has approached this subject from the viewpoint of the chemist. I shall discuss it from the standpoint of those who apply data of this kind to the loading of transformers.

So far as the data given in the recent report by the AIEE transformer subcommittee on "Cooperating Aging Tests" are concerned these tests were not comprehensive enough to prove anything but the limited purpose for which they were made, namely, to settle the question of whether the tensile strength of insulation in oil protected from air decreases to, say, 40 per cent of the initial strength and then ceases to decrease any further for an indefinite period of time.

Figure 1. Manila paper with cloth and fuller board sealed in oil under nitrogen. (Test points taken from Figure 4 of Dakin's paper)

They proved that the material does not cease to deteriorate as had been contended by some investigators but continues to deteriorate at an unbroken rate until its life is gone. The test points are too few and scattered to establish any theory of aging.

The author's proposed method of plotting aging data differs in two ways from that generally used by previous investigators. First, he states that tensile strength should be plotted on a log scale and time on a linear scale, as shown in Figure 3 of the paper, instead of the reverse; and second, when plotting time versus temperature to produce a given per cent of initial strength, say 20 per cent, the time should be on the log scale while the temperature scale should be of a decreasing order proportional to the reciprocal of the absolute temperature (as shown in Figure 6 of the paper) instead of on degrees centigrade scale.

Referring to the first point, the method of plotting advocated by Dakin is not new. The AIEE data plotted in Figure 3 of the paper were plotted exactly the same way in the AIEE report. However, the reason for the choice of the scale used was convenience whereas Dakin wishes to establish it as a preferred method. The data in the AIEE report are too few to establish such a preference. Dakin's own data, shown in Figure 4 of the paper and replotted as a straight line in his Figure 5, definitely contradict that method of plotting, for in his Figure 5 the empirically determined ordinate scale is very different from the log of the tensile strength. In fact, I have taken those data and plotted them by the conventional method in Figure 1 of the discussion (strength versus log of time), and it will be seen that they fall as nearly on a straight line as they do in Dakin's Figure 5 (log of strength versus time).

Limited portions of data can frequently be plotted as a straight line by more than one method. When curves are plotted on linear co-ordinate paper, the portions of practical interest have the appearance of being asymptotic to the axes. However, the majority of published data covering wide ranges of time for different temperatures show that a straight line is obtained when tensile strength below approximately 80 per cent initial is plotted against log of time in the usual manner. Clark's voluminous data are excellent examples. We are usually interested only in strengths of 50 per cent and below.

Referring now to the second point, namely, that a straight line is obtained on semilog paper if time is plotted on the log scale and the temperature scale is made proportional to the reciprocal of the absolute temperature as shown in the author's Figure 6. Dakin claims that Clark's data fall on a straight line when plotted this way, as shown on the bottom line of Figure 6 of this paper. But Clark's 100 degree test point is incorrectly plotted in Dakin's paper. It should have been at approximately 500 weeks instead of 95 weeks. The 135 and 120 degree points are plotted correctly. If all points are correctly plotted, the line is not straight as shown but has a decided bend.

To see how Clark's data fall on the scale that Dakin suggests for plotting aging tests, I have plotted Figures 2 and 3 of the discussion for the 50 per cent and 25 per cent strengths for 100, 120, 135 and 200 degrees centigrade lines taken from Figure 4 of Clark's paper.[1] Figure 2 of the discussion shows the data plotted on semi log paper using the temperature scale suggested by Dakin. It will be seen that a straight line cannot be drawn through any three of the four test points. Figure 3 of the discussion shows the same data plotted in the usual way. The lines will be seen to be straight from 200 degrees down to 120 degrees and then to bend upward. The reason for the upward bend of the lines from 120 down to 100 degrees centigrade is seen in Figure 7 of Clark's paper which shows that the doubling of the life for a decrease of 8 degrees does not apply for temperatures below approximately 115 degrees centigrade. At approximately 100 degrees centigrade the doubling relation occurs for a change of approximately 5 degrees centigrade.

I was very much interested in Figure 9*a* of Dakin's paper in which he works out the effective average temperature of an over load that produces 135 degrees centigrade hot-spot for approximately 3 hours during a 12-hour period. To see how the effective average temperature, when derived by the method that I have used, compares with that obtained by Dakin's method I resolved the hot-spot curve shown in Figure 9a into a rectangle and triangle, and integrated these two areas, as shown in Figure 4 of the discussion. This method of integration shows that the effective average temperature when derived by the simpler method is 123.3 degrees centigrade, as compared with 125 degrees centigrade when worked out by Dakin's more elaborate method. The difference in the two answers is negligible in this case, but in another one we find the following very significant difference.

According to Dakin's aging data it would require 1.415 years (74 weeks) to reduce the tensile strength of paper (with some cloth and pressboard present) to 20 per cent when operated at an effective average tempera-

Figure 2. Temperature, degrees centigrade (reciprocal absolute temperature scale)

Figure 4 (above). High temperature overload cycle shown in Figure 9a and solution for effective average temperature by usual method

Rectangular Area a, b, c, d — Units

$$P = te^{0.0865T} = 2.8e^{0.0865\times135} = 329{,}000$$

Triangular Area e, b, f

$$P = 6\left[\frac{e^{0.0865\times135} - e^{0.0865\times90}}{0.0865(135-90)}\right] = 177{,}000$$

Total = 506,000

If $506{,}000 = 12e^{0.0865\times T}$

$T = 123.3$ versus 125 degrees centigrade given in Figure 9a

P = aging units, $e = 2.718$,

T = maximum hot-spot, t = time

ture of 125 degrees centigrade. The data given in Figure 4 of Clark's paper show that it would require approximately 25 weeks or 1/3 the time. Here is a difference of 3 to 1. Which one is the more correct?

Recently I made some aging tests which check Clark's data very closely. In these tests strips of manila paper were inserted between turns of transformer-type coils having plenty of pressboard around them, as indicated in Figure 5 of the discussion. These coils were immersed in 25 to 40 degrees oil, heated by current to the temperatures of 195, 179, and 157 degrees centigrade as shown in left side of Figure 6 of the discussion. The temperature was observed by thermocouples placed against the paper strips. It will be seen that these aging tests, made under transformer conditions, check quite well Clark's test-tube data on paper alone. My 195 degree line, when proper allowance is made for the 5 degree difference in temperature, checks reasonably well Clark's 200 degree line. The two right-hand 135 degree lines extrapolated from my 179 and 195 degree test data, are in very close agreement with Clark's 135 degrees centigrade test data.

In conclusion, it is my opinion that Dakin has not presented sufficient evidence to justify the use of his more complicated ways of plotting and computing insulation aging values. The more comprehensive series of tests reported in Clark's 1942 AIEE paper[1] support the usual method of plotting the tensile strength on the linear scale and time on the log scale but do not support the method advocated by Dakin.

Herman Halperin (Commonwealth Edison Company, Chicago, Ill.): This paper emphasizes the need and value for the electrical engineer to consider chemistry theory in studies of deterioration of electrical insulation. The graphical representation of data, particularly in Figure 8 of the paper clearly indicate how widely different kinds of deterioration phenomena behave similarly as a function of temperature (although the amount of loss of life at a given temperature varies between the phenomena). It is implied in Dakin's paper, as well as in other similar literature, that the magnitude of deterioration caused by operation at different temperatures may be simply determined by adding the deteriorations at each of the operating temperatures that are indicated by the steady-temperature tests. For example, continuous laboratory tests might indicate that operation at 100 degrees centigrade for one year would cause X per cent deterioration and that operation at 150 degrees for two days on another piece of the same material would cause Y per cent deterioration, but some of our test data suggest that when such a combination of tests is made on one given sample, the resultant deterioration is considerably larger than X plus Y per cent.

I have recently arranged for further tests to check this finding. Oil-filled single-conductor cable is being used as the basic samples in the tests. The test setups are being varied to simulate conditions ranging from a sealed system free of air and moisture to a loosely-gasketed system, in order to obtain data applicable to different transformer types and to paper-insulated power cable.

T. W. Dakin: Montsinger and Halperin have raised some very pertinent points concerning the subject discussed in this paper. Montsinger has treated some particular points in some detail. In answer to Montsinger, it can be pointed out that in this paper a rational theoretical approach to the subject of insulation deterioration has been attempted, in contrast to the purely empirical approach with which Montsinger is familiar. Montsinger must admit that a chemical process is the reason for mechanical deterioration of the insulation. He, therefore, should not object to the application of chemical principles to this problem.

The author does not wish to defend any particular data either newly presented in this paper or obtained from the literature. Data which were available at the time the paper was written were used to illustrate the principles discussed. The tests sponsored by the AIEE transformer subcommittee on Co-operative Aging of Transformer Insulation seemed to have been conducted under fairly well controlled conditions, a feature not always present in the case of many aging tests which are made. It is difficult to fit any theory to widely divergent test results. Therefore, data obtained under well controlled conditions are necessary to

Figure 5. View of coil used for making aging tests on 0.003 inch manila paper strips inserted between turns as shown

Figure 6. Comparison of aging of manila paper at 157, 179 and 195 degrees centigrade in transformer coils in oil (25 to 40 degrees centigrade) with Clark's and Dakin's data

Figure 7. The time in weeks aging at elevated temperatures for manila paper to decrease under various conditions to 20 per cent of original tensile strength, plotted on a logarithmic scale versus the reciprocal absolute temperature

check any theory. It seems that Montsinger is unjustified in stating that the Figure 5 of the paper contradicts the method of plotting proposed by the author. The author did not say that all data should be plotted with the logarithm of the physical property (tensile strength) against the time. In the paper, the discussion following equation 3a pointed out that a more complicated function, rather than the logarithm, of the physical property would in many cases be proportional to the time, equation 4a.

The empirical method of plotting used by Clark in which he reverses the scales and plots the time logarithmically has the objection that it does not have a logical starting point at zero time. That method of plotting, although it has been used by Clark in several papers, should hardly be called conventional.

Montsinger is correct in saying that the 100 degrees centigrade test point taken from Clark's data was plotted incorrectly in Figure 6 of the paper. However, when it is plotted correctly, as Montsinger did in his discussion in Figure 2, together with the 200 degree centigrade test point, the four points fall on, or are symmetrically scattered on either side of, a straight line. This can be verified by drawing a straight line through the points of curves *A* and *B* of Montsinger's Figure 2. The data of Clark which give the time to reach 20 per cent of original tensile strength in oil under nitrogen are plotted in Figure 7 of this discussion. The line drawn through Clark's data with the 100 degrees centigrade test point plotted correctly, and the 200 degrees centigrade test point added then falls parallel to the other lines in the Figure 6 of the paper, which are reproduced in Figure 7 of this discussion. The parallelism of these lines indicates that the reaction mechanism of cellulose deterioration is probably the same under all the conditions given. The fact that they do not fall on top of each other indicates there is some other chemical substance than the cellulose which is affecting the reaction or entering into it, and which is present in different amounts in the different cases.

It seems that Montsinger is unfair when he draws a straight line through scattered points in his Figure 6, but does not draw a straight line in his Figure 2, but draws a curve to touch each point exactly. There seems to be a similar amount of scattering in both cases. In one case, Montsinger wanted to show a linear relation so he drew a straight line. In the other case, he did not want to show a straight line so he drew a curve.

In Figure 3 of Montsinger's discussion, the points decidedly do not fall symmetrically on either side of a straight line. The points show a decided trend with the lower temperature points indicating a curve upwards. This verifies, as do also the statements of Montsinger, the point the author establishes theoretically in the paper, that the temperature interval in which the reaction rate doubles decreases as the temperature decreases. It is, therefore, as even Montsinger admits, not possible to apply his 8 degree rule below 115 degrees centigrade, where the rule seems to change to about a 5 degree rule. Compare this with Figure 1 of the paper. Montsinger may find upon investigating the origin of the 8 and 10 degree rules that they came originally from chemists who many years ago proposed them as rough approximations of the temperature coefficients of the chemical reaction rates. Since Montsinger has accepted and used these rough approximations proposed by chemists, he should not object to using the more exact expressions from which his 8–10 degree rule was borrowed.

Montsinger it seems is also unjustified in referring to the integration of the curve of Figure 9*b* of the paper as being more elaborate. The integration of this curve can also be done roughly by the use of triangles and rectangles as Montsinger has done. There is no mathematical calculation at all involved in converting from Figure 9*a* to 9*b* by the procedure given in the paper, and upon close examination, it should be seen that the method given in the paper is actually simpler than Montsinger's equations which involve fractional exponents. Familiarity, of course, makes one method or the other seem simpler.

There is no problem at all in answering Montsinger's question: "Which is the more correct?" Clark's data or the data reported in the paper, which was obtained by McCulloch. The answer is that both are correct for the conditions under which the respective aging tests were run. The conditions were somewhat different in the two cases, and, therefore, the time to deteriorate may be and is different.

Montsinger's experiments, which he reports in his discussion, are very interesting and more of that type of testing should be encouraged. No matter how the data are treated after it is obtained, it cannot be emphasized too much that the testing conditions should reproduce as closely as possible the conditions in the apparatus. On this point, almost every one should agree. Peculiarly enough, the data of Montsinger obtained with transformer conditions seem to agree better, upon close examination, with the extrapolated AIEE tests data represented in this paper than with the test results of Clark. Figure 7 of this discussion is the same as Figure 6 of the paper, with the exception that the 100 degrees centigrade test point of Clark's data has been replotted more correctly, his 200 degrees centigrade test point added, and the other lines extrapolated to 200 degrees centigrade. In spite of this rather close agreement of the extrapolated lines with Montsinger's experimental points, it should not be regarded as an unqualified verification of the theory, inasmuch as the experimental conditions were not entirely the same in the case of the AIEE tests as in Montsinger's tests.

In Halperin's discussion, he has raised a good point, concerning the additivity of

deterioration effects at different temperatures. Most experimental data of any accuracy reported to date have been taken at constant temperatures. There should be well controlled tests of aging run over temperature cycles in which the temperature is measured accurately and the other conditions controlled. It is true that in this paper it is assumed that the amounts of deterioration at different temperatures are additive in a sense. This is true of chemical reactions. Whether or not it applies in the complex case of electrical insulation has yet to be proved satisfactorily. But until there is good evidence to the contrary, the best we can do is to assume that additivity applies.

In summary, it should be restated that in this paper it has been attempted to set down some principles which should apply in the study of insulation deterioration, and to show by example how they apply to some existing aging data. The author admits that extrapolation from data is dangerous, but in lieu of no information at all, it is best to extrapolate by recognized theories than to guess.

Tests to confirm or deny this or any theory should be encouraged. The methods of plotting aging data described in this paper have a theoretical basis and should therefore be preferred over empirical methods of plotting or extrapolating data in cases where the theory has been shown to apply correctly.

"Terratex"—A Thin Flexible Inorganic Insulation

T. R. WALTERS
MEMBER AIEE

Synopsis: A limited number of inorganic insulations has been available to the designer, as compared with the variety of organic materials on the market today. The development of terratex, a thin, totally inorganic paper-like sheet, fills a gap in the inorganic insulation field. Laboratory tests and four years of service experience indicate that its excellent high-temperature characteristics and other properties may be utilized wherever it is advantageous to use inorganic insulation.

ONE of the major factors which has limited the output rating of electric equipment has been the deterioration of organic insulations at high temperatures. To aid in obtaining higher ratings from the same size equipment, terratex, an inorganic insulation, has been developed to take the place of certain commonly used organic sheet insulations.

To fill the every day needs of the designer, a wide variety of organic sheets and tapes has been developed. The sheets are usually cellulosic papers and pressboards, whereas cellulosic fibrous materials take the form of yarns or woven tapes and cloths. Paper and pressboard are used as widely as possible because of their relatively low cost and excellent dielectric properties which result in good utilization of space. Yarns and fabrics are characterized by higher costs and poorer dielectric properties, consequently, they are used only where their better physical properties are required. Years of operating experience and laboratory tests have resulted in standardizing on a maximum temperature of 105 degrees centigrade for organic insulations, which are listed[1] as class *A*.

In the class *B* insulation field,[1] with a corresponding maximum temperature limit of 130 degrees centigrade, the designer is limited by the small number of useful materials. Mica sheets and tapes are expensive and often difficult to use. Commercial asbestos papers usually contain about 15 per cent of cotton fibers and starch, and are thick and weak dielectrically. Fiber glass yarns and cloths are excellent mechanically and thermally, but are fairly expensive and in themselves only spacers depending on varnish filling for dielectric strength. There has been no inorganic counterpart of the relatively low-cost high-dielectric-strength organic papers.

Paper 48-20, recommended by the AIEE basic sciences and transformer committees and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted November 12, 1947; made available for printing December 29, 1947.

T. R. Walters is with the electrical research section, works laboratory, General Electric Company, Pittsfield, Mass.

Figure 1. Terratex tape

Development of Terratex

Consideration of the problem of providing an inorganic counterpart of organic paper led to the conclusion that a flexible inorganic sheet would require a fibrous base similar to that of the cellulosic fibers used in organic papers. Two inorganic fibers were known—asbestos and glass. Neither can be "hydrated" in the way cellulose fibers are in paper making.

As glass fiber is better electrically than natural asbestos fiber, attention was given to it first. After many trials, a mineral filler and binder was developed to use with it, and a method developed to make a continuous sheet of this combination which bore a strong resemblance to paper. This sheet could be made in thicknesses of a few thousandths of an inch, had high tensile strength, and good dielectric strength. However, it lacked sufficient flexibility to be wrapped on wire.

Asbestos fibers are more flexible than glass, but they contain many impurities and conducting particles which limit their use as dielectrics. Means were found for preparing the fiber to much smaller dimensions, and for the removal of impurities and conducting particles to a degree not considered commercially feasible in the past. Means were also found for combining this purified fiber with the mineral binder and filler by a special paper-making process on fairly standard paper-

making machinery. The resulting sheet (Figure 1), which has found a number of uses in electric apparatus, is thin, flexible, 100 per cent inorganic, and very similar in appearance to cellulosic paper. All of the following data and uses are based on this asbestos-type material.

Properties of the Sheet—Untreated

This new sheet has been produced as thin as one mil. Regular thicknesses are 1.5, 2, 3, 4, 5, 8, and 10 mils. So far, the greatest use has been for wire covering with the 3-mil material. During the past three years, an average of 66 pilot-plant paper mill runs per year have been made of this thickness material for this purpose. The range and averages of thickness, tensile strength, and dielectric strength for the three years are shown in Table I. Five tests were made to obtain an average for each lot; the dielectric strength tests being made at prevailing room conditions. Data for 1947 are incomplete.

At present, the physical properties of tear and tensile strength, while not initially as high as those of commercial asbestos papers, are sufficiently high for effective use and extremely stable with time at high temperature. In aging tests such as are widely used on class *A* insulations, where the decrease in tensile strength is measured against time at various temperatures, no decrease is found in tests of many months duration. At 175 degrees centigrade, a temperature which reduces cellulose to a useless cinder in a matter of hours, terratex retained its original tensile strength after 710 days. Commercial asbestos paper containing the usual percentage of organic material had dropped 50 per cent to equal the strength of terratex in ten days and had lost 90 per cent of its initial strength in 87 days.

Besides being unaffected by long time exposure to the high temperatures it might be subjected to in electric apparatus, terratex is completely noninflammable. It can be brought to a bright red heat (850–950 degrees centigrade) in a Bunsen burner flame, with neither ignition nor melting of the sheet. In fact, it retains a dielectric strength in the order of 100 volts per mil at 800 degrees centigrade.

At room temperature the dielectric strength of this sheet is in the order of 300 volts per mil. Because of the drying out of absorbed water, this value increases to about 500 volts per mil at 300 degrees centigrade and gradually drops back to 300 volts per mil at 500 degrees centigrade. At this and higher temperatures the material becomes brittle in much the same way that "Muscovite" or white mica does, due to loss of water of crystallization. For these tests, two sheets of 3-, 5-, or 10-mil terratex were placed between 5/8-inch-diameter platinum electrodes. The bottom electrode was insulated by several more sheets placed over a flat U of resistance wire used as a strip heater. This assembly was set into the center of two magnesia blocks, with a thermocouple to measure temperature. Regular American Society for Testing Materials[2] 60-cycle 1-minute step-by-step tests were used.

It is of interest to note that this trend of increasing dielectric strength with increasing temperature is not always exhibited by inorganic insulations. Figure 2 shows, for example, that such well-known dielectrics as porcelain and Pyrex glass become quite conducting at temperatures[3] above 150 degrees centigrade. These data on glass are verified by Littleton and Morey[3] who show about the same reduction in dielectric strength with temperature over the same range reported here. Thus, while they may be nonaging, their use as dielectrics at the higher temperatures is definitely limited.

Properties of Treated Terratex

Although much better from both a thermal-life and dielectric-strength standpoint than commercial asbestos paper, terratex at present is initially no stronger physically, as noted earlier. This, coupled with the fact that this sheet can be made much thinner than commercial asbestos papers, makes the actual tensile strength in pounds per inch of width quite low. Since all class *B* coils are given some type of varnish or compound treatment eventually for structural and moisture retardant reasons, the sheet is generally pretreated to facilitate handling. This treatment increases the tensile strength of the 3-mil wire-covering type of terratex from an average strength of 300 pounds per square inch to a minimum of 4,000 pounds per square inch, which is more than ample for high-speed wire covering. The varnish used can be one which previous experience has shown to be good for high temperatures, although no varnish available today has heat resistance equal to that of terratex sheet.

Varnished, the sheet naturally takes on some of the properties of the treating material. Dielectric strength tests have been made on alkyd, asphalt, phenolic, copolymer, and silicone treated sheets. The results of three of these, on "burn-out" dielectric tests run to the same

* Single lot—remainder well above 200 volts per mil.
** Not for complete year.

temperatures as the all-inorganic untreated sheet are shown on Figure 3. A minimum of varnish was used in treating these sheets. They were barely saturated, so that no surface film existed, as it was desired to limit dependence on organic materials to a minimum.

Treated cellulosic sheets carbonize and disintegrate when subjected to overtemperatures for a length of time. Terratex has been found to retain its naturally high initial dielectric strength when the treating compound is "cooked" out of it, while inorganic fabrics under the same conditions become merely "spacers" of low dielectric strength.

With loss of varnish, all flexible inorganic sheets including mica lose their initial moisture resistance. Table II shows the effect of moisture on lightly treated sheets of 3-mil terratex. Designers should note that the effect of water is greater on terratex than on the more familiar kraft paper. The data also indicate that a better varnish will result in improved properties.

To obtain these data, the dielectric strength was measured at 60 cycles between 2-inch-diameter electrodes with edges rounded to 1/4-inch radius. Breakdown was taken on single sheets in air at temperatures indicated, with continuous rise of voltage so as not to dry out the "wet" samples. A "25 degrees wet" measurement was on sheets which were immersed in tap water for 24 hours then removed, blotted dry, and tested immediately. Each value is the average of five measurements.

Methods of Use

So far all manufacture and treatment of this sheet has been on a pilot-plant basis, so that its uses have been limited. The most important use has been on large magnet wire. Other uses are as layer insulation, mica backing, and a mica substitute.

Magnet Wire

Pretreated 3-mil tapes have been applied to a wide range of rectangular wire sizes, from 90 mils square up to large flat conductors. They were applied in two or more butt-wrapped layers in much the same way that paper tapes are used for class *A* apparatus, except that they were "bonded" by applying an adhesive to the wire as the tape was wrapped on. In cases where the coil winding operation involved severe abrasion, an outer wrap of glass fiber was applied and varnished, corresponding to the cotton yarn that is often used over paper covered wires for mechanical protection.

Figure 4. Wire sample for thermal aging test

With a 12-mil build of insulation (six mils on a side) this terratex wire has a breakdown strength of 160 volts per mil or better. This compares with a strength of 60–80 volts per mil for felted asbestos wire, and of 80–100 volts per mil for varnished glass yarn wire, of the same insulation thickness tested under the same conditions. The copolymer treated material was used for the wire insulation to obtain a good balance between electrical, thermal, and physical properties.

For these tests, samples of wire six inches long were used; each individual wire being covered for four inches with lead shot. A 60-cycle potential was applied between the conductor and the shot and gradually increased to puncture.

Additional laboratory tests have been made on pairs of each of these three wire insulations. These data are shown later in Table III under the discussion of thermal aging. The results obtained in this manner are higher than the above figures, but bear the same relation to each other. The copolymer treating material is an elastomer, and imparts a degree of stretch and tensile strength to the tape that makes it well adapted to wire covering. Such insulation yields when the wire is bent, instead of rupturing the way unstretching cellulosic papers do.

Since the copolymer is also thermoplastic, consideration was given to what might happen to wires under short-circuit conditions, where high temperatures and high mechanical stresses occur simultaneously. Stacks of rectangular wire three high and three wide were tied together and put through factory varnish treatment. They were prepared for rapid connection to a circuit applying 110 volts between adjacent turns, and then preheated to 175 degrees centigrade. When fully up to temperature, they were taken from the oven, placed immediately between the platens of an hydraulic press which were also at 175 degrees centigrade, and the connections made. The pressure was then increased gradually until an electrical failure developed. This occurred at a pressure of 1,000 pounds per square inch, which was considered more than adequate.

Layer Insulations

Depending on the voltage between layers, size of coil, and other factors, any one of the available thicknesses of terratex may be used as a layer insulation for high-temperature operation. The thinner sheets generally will require pretreatment to facilitate handling, while the 5-mil or thicker sheets may be either presaturated or used untreated and impregnated during the coil treatment.

In either case, this new sheet makes it possible through its inherent high dielectric strength to obtain a high space factor with minimum dependence on varnish. If it is desired both to saturate and to coat

Table II. Effect of moisture on the short-time 60-cycle dielectric strength of lightly treated 3-mil terratex

Paper	Varnish	Thickness, In.	Dielectric Strength, V Per Mil			
			25 C	100 C	150 C	25 C Wet

Terratex	Phenolic	0.0040		245	222	93
Terratex	Asphaltic	0.0035	421	448	368	195

Figure 5. Terratex insulated coils for 500-ampere air-cooled arc-welding transformer

the sheet with varnish, as some cellulosic papers are, higher dielectric strengths can be obtained. For example, a typical saturated 3-mil sheet has a dielectric strength of 400 volts per mil. Saturated and coated, the same sheet will have a strength of 600 volts per mil or more.

Mica Backing

Composite sheets of insulation often are used to fill the particular requirements of certain types of apparatus. Flexible mica generally has a sheet of thin organic paper pasted to each side to give it tensile strength and to hold the mica flakes in position. Despite its mica content, such a sheet is not satisfactory for temperatures so high that the cellulose disappears in time leaving a loose structure.

To obviate this difficulty, thin varnished cloths of glass fiber have been used in place of the paper. This results in a sheet with excellent thermal life and physical properties, but of very high cost.

Figure 6. Terratex insulated 500-ampere air-cooled arc-welding transformer

Replacement of one of the two 2-mil varnished glass cloths with a 1.5-mil varnished terratex on a flexible mica sheet which totaled 10 mils, resulted in a composite of equal thermal life, a slightly higher and more uniform dielectric strength, ample tensile strength, and lower cost. A quantity of such sheets was used successfully during the war in certain very compact rotating equipment for aircraft. To save weight, this equipment was designed to operate at high temperature.

Mica Substitute

Nominal 5-mil flexible mica sheets, particularly of the machine-made type, are quite variable in thickness (2–12 mils). At the thin spots the breakdown voltage is quite low. In comparison, 5-mil varnished terratex is a continuous, homogeneous class *B* sheet with a thickness variation of not more than 0.5 mil, and an equally uniform dielectric strength of about 400 volts per mil.

Comparative burnout tests with overcurrent have been made on windings with (*a*) organic-backed mica and (*b*) terratex used as insulation between layers. In time, the organic backing and the adhesive disappeared, leaving only the mica insulation. Under the same conditions, the terratex remained in position, providing practically the initial insulation.

Thermal Stability of Treated Terratex

Again following the conventional aging test for class *A* insulations, a large number of strips representing 30 combinations of different varnishes on terratex and on commercial asbestos paper were aged in a 175-degree-centigrade oven. Periodically, several strips of each type were removed from the oven and tested for tensile strength. From these data it was concluded that

1. In general, the use of an organic material as an integral part of the asbestos sheet results in a material of short life.
2. After varnishing, such materials have a three to five times better life span.
3. When a totally inorganic paper such as terratex is varnished, its life span is at least six times that of a varnished asbestos paper containing organic material as an integral part.

When the tensile strengths of most of the varnished terratex samples leveled off at the same value as that obtained on untreated terratex, it was concluded that this type of test had far less meaning on inorganic base materials than on organic insulations. Hence, a test more nearly representative of conditions of use was adopted in which the insulation was

Figure 7. Terratex insulated dry-type transformer for load center unit substation

tested on wire, as layer insulation, and as spacers. As this development has progressed furthest in its application to wire insulating, most of these thermal aging data available at present relate to wire.

The samples consisted of pairs of 0.095-by-0.295-inch wire, insulated to 0.012-inch increase in dimensions with the three types of material under comparison. These were glass fiber, felted asbestos, and terratex. The flat sides of two 9-inch lengths of wire were held tightly together over the middle six inches with glass-fiber tying cord. The ends were flared to prevent flashover, and the samples were factory treated in phenolic varnish (see Figure 4).

On the assumption that loss of moisture protection was a limiting factor in the use of open dry-type apparatus, it was decided to use power factor measurements after exposure to high humidity as a criterion in judging the useful life. After measuring the initial power factor and dielectric strength between the conductors of several pairs, five sets of each type of wire were placed in a circulating air oven running at 175 degrees centigrade. At about

5-day intervals, the samples all were removed from the oven, cooled to room temperature, and placed in a humidifier operating at a 90 per cent relative humidity at 90 degrees Fahrenheit. After 24 hours the power factor was measured, and the samples returned to the oven. This cycle was repeated until a high power factor was obtained. The "break" in the power factor versus time curve was quite sharp in each instance. Also, it occurred at very nearly the same time on all samples of the same type. Dielectric tests were again made at this end point. (See Table III.)

In this series of tests the terratex insulated wire had double the breakdown strength of the other insulation of equal thermal life. This ratio was maintained after both had dropped in value due to thermal deterioration of the varnish.

Use in Transformers

To gain experience with this new material, limited production use of it has been made. Starting in 1943, a number of arc-welding transformers (see Figures 5 and 6) have been built each year using terratex insulated wire. In addition, a smaller number of dry-type load center unit substation transformers (see Figure 7) of much higher voltage rating, have been built over the same time period. No service failures have yet been encountered.

Table III. Dielectric properties of wire samples aged at 175 degrees centigrade—0.012-inch insulation

Sample	Per Cent Power Factor	Kv Breakdown at Room Temperature	V Per Mil
Double glass + phenolic varnish—Initial	3.0	2.6	216
End (51 days)	87.3	1.7	141
Felted asbestos + phenolic varnish—Initial	23.0	2.0	167
End (22 days)	96.0	2.0	167
Double Terratex + phenolic varnish—Initial	17.2	5.2	433
End (50 days)	88.9	3.4	283

Conclusions

1. A versatile new type of dielectric has been developed which fills a gap in the field of high temperature electrical insulation.

2. This flexible inorganic paper-like sheet is, by virtue of its method of manufacture, potentially less costly than the few other flexible high temperature insulations available at present.

3. This sheet possesses an unusual combination of dielectric strength, thermal life, and incombustibility.

4. Utilization of these properties by the designer can result either in improved space factor or a higher factor of safety.

5. Service experience in certain types of electric apparatus has to date shown no defects.

Electronic Circuits of a Supersonic Reflectoscope

RALPH B. DeLANO, JR.
ASSOCIATE AIEE

THE SUPERSONIC reflectoscope is a device for the nondestructive testing and measuring of solid parts. It operates by sending pulses of supersonic energy into the material under test and measuring the length of time it takes these pulses to penetrate the material, reflect from the opposite side or an internal defect, and return to the sending point. Reflections are caused by the abrupt changes in elastic properties or density existing at defects and boundaries. A defect having a dimension greater than one-eighth inch when projected on a plane perpendicular to the axis of the supersonic beam may be readily located when ten feet from the surface, but the dimension of the defect in a direction parallel to the axis of the beam may be very small—in fact, the two faces may be in intimate contact.

Such an instrument has many practical uses. Fatigue cracks in axles, shafts, crank pins, and other metal parts may be found without disassembling the machine, provided the end of the part to be tested is accessible. Hydrogen ruptures in steel billets, laminations in plates, and defective welds are also among the defects which may be detected with the supersonic reflectoscope. The use of a reflectoscope in testing the shaft of a small generator is shown in Figure 1.

Figure 2 shows a typical reflectogram. The initial pulse appears at the left of the cathode ray tube trace, and at the right is seen the reflection from the end of the shaft. The reflection in the center is from a defect. Its distance from the surface may be obtained by counting the number of square wave cycles appearing between the pulse and the reflection from the defect.

One of the important electronic features of this device, as developed by Floyd A. Firestone, is the fact that a short duty cycle is employed and this permits operation with a-c power supplied directly to each tube without the use of any rectifiers. This paper gives a discussion of the circuits in the instrument and their operation with raw a-c power.

Functions of the Circuits

The electronic circuits of this reflectoscope may be divided into the following sections—sweep, delay, pulse generator and crystal or searching unit, main amplifier, and marker circuit.

Figure 3 shows the relationship between these sections. The sweep, which is synchronized to the supply frequency, starts the cycle of events and generates a voltage which is used to move the cathode ray horizontally across the face of the tube. The sweep also provides a synchronizing signal to start the marker circuit which puts distance markers on the tube face. A second synchronizing signal from the sweep circuit trips a delay circuit. This delay circuit in turn fires the tube which generates the pulse. The pulse is impressed across the crystal and causes the latter to generate a supersonic wave train in the part being tested. This pulse is also impressed on the amplifier whose output is connected to the vertical plate of the cathode ray tube. Reflections of this wave train strike the crystal where they are converted back to electrical pulses and impressed across the input of the amplifier. The output of the amplifier being connected to the vertical plate of the cathode ray tube, the time interval between the pulse and the reflections can be measured on the face of the tube. A circuit diagram of the instrument is shown in Figure 4.

Sweep

The sweep is generated by an inert gas thyratron tube, V_9, discharging capacitors C_2 and C_3. The gas tube is synchronized to the power supply frequency by having a sine wave of the supply voltage reduce the grid bias voltage to the critical value. Variation of the magnitude of the grid signal by means of potentiometer P_6 changes the point in the 60-cycle voltage at which the tube fires. Capacitor C_2 must discharge through potentiometers P_2 and P_3 as well as through the tube. Potentiometer P_2 is ten times the value of potentiometer P_3 and consequently controls the discharge time of capacitor C_2. A small portion of the discharge voltage is selected by potentiometer P_3 and applied to the grid of V_{10}. The output of V_{10} is applied directly to one horizontally deflecting plate of the cathode ray tube and through tube V_{11} to the other deflecting plate. Consequently, potentiometer P_2 controls the time required for the cathode ray tube spot to sweep across the screen, and for a given value of potentiometer P_2 the other potentiometer P_3, controls the magnitude of the sweep.

The general shape of the sweep voltage is shown in Figure 5. The cathode ray tube spot is normally biased off the right side of the screen, and the sweep voltage moves rapidly across the screen to the left side and then back at a rate determined by the setting of the sweep time potentiometer as previously explained. If the thyratron were not kept fired during the sweep and for some time thereafter, the sweep would be interrupted and the cathode ray tube spot would move to the left again. This is prevented by inserting a small resistor between the plate of the thyratron and the capacitors C_2 and C_3.

One of the advantages of this type of

Paper 48-21, recommended by the AIEE joint subcommittee on electronic instruments and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted November 5, 1947; made available for printing December 23, 1947.

RALPH B. DELANO, JR., is research engineer with Sperry Products, Inc., Hoboken, N. J.

Figure 1. Testing the shaft of a small generator with a supersonic reflectoscope

sweep circuit is that by adjusting potentiometer P_3 so that a small value of resistance is in the circuit and increasing the value of the other potentiometer, P_5, the sweep piles up at the left side of the screen and reflections further along at the right may be seen on a more expanded scale than would normally be provided by an exponential or even a linear sweep.

When testing for defects near the surface, the exponential sweep possesses a distinct advantage over the linear sweep in that it provides good resolution on the screen for the area being tested and yet enables one to observe the back reflection. The back reflection provides a continuous check on the amount of energy being transmitted into the part under test, and this is important because occasionally surface irregularities cut down the amount of energy entering the part. Also some types of defects or a large number of small defects are more readily found by a diminution of the back reflection rather than a distinct reflection from the flaw itself.

Some loss in the brilliancy of the cathode ray tube trace is caused by the choice of a repetition frequency as low as 60 cycles per second. If an appreciably higher repetition frequency were used, however, material having low absorption would not attenuate the supersonic energy sufficiently between pulses. As a result, reflections of the previous wave train would appear on following traces and might be mistaken for defects.

A repetition frequency near 60 cycles being desirable for other considerations, it is advantageous to have it synchronized with the power line to prevent beat phenomena from causing jitter on the face of the cathode ray tube. Another advantage of synchronizing with the supply line frequency is that it permits the electronic tubes to be operated with a-c power, as will be discussed later.

Delay Circuit

An adjustable delay between the start of the sweep and the generation of the pulse is necessary with this type of sweep circuit because the time of the forward trace increases as the sweep time is increased. When a gas tube of the type used in this instrument is fired, a sharp positive jump in grid voltage occurs at the same time as the drop in plate voltage. This grid signal is differentiated and used as a trigger signal for a flip-flop circuit. The output of the latter circuit is differentiated again, yielding a negative pulse whose delay with respect to the input signal may be varied by adjusting potentiometer P_4. This pulse is inverted and amplified by tube V_{13}, whereupon it is applied to the grid of the pulse tube V_1, causing it to fire. In this manner the sweep appears on the cathode ray tube before the pulse, and the latter may be moved back and forth along the sweep as required.

Pulse Generator

A 1,000-volt exponentially damped pulse is generated when the gas tube V_1, fired by a signal from the preceding tube, discharges the capacitor connected across it and shock excites the tuned circuit L_1 C_1. A series potentiometer, P_1, controls the decay and magnitude of the pulse. The frequency of the pulse is the same as the supersonic testing frequency, and normal testing frequencies are 1/2, 1, $2^1/_4$, and 5 megacycles per second, although a continuous coverage in overlapping ranges is provided by the variable capacitor and the switch which selects the appropriate inductance. It also has been found desirable to switch the discharge capacitor when changing the pulse inductance, a smaller capacitor being used as the frequency is increased.

The pulse voltage appearing across the inductor and potentiometer is transmitted by a cable to the searching unit. This unit is an X-cut, piezoelectric quartz plate cemented to a bakelite button so that it may be held in the hand against the part being tested. The crystal is one-half wave length thick and therefore resonates at the pulse frequency. It vibrates in a piston mode and transmits these vibrations through a film of oil into the part being tested as a supersonic wave train. This wave train is reflected by the boundaries of the part being tested or by inhomogeneities therein, and upon striking the crystal it is reconverted into electrical energy.

Intermediate Frequency Amplifier

The pulses generated by the reflections are of the order of a few millivolts and must be amplified before they can be displayed on a cathode ray tube. They are mixed with a voltage generated by the local oscillator tube V_2 and its associated circuit and then amplified by the intermediate frequency amplifier comprising tubes V_3 through V_8. The amplifier is of the broad-band type, amplifying frequencies between 9 and 12 megacycles, but the output transformers are arranged so that the windings may be switched, giving an output peaked at 11 megacycles or tunably peaked and adjustable between 8.75 and 11 megacycles, as well as a broad output. The amplifier gain is much greater with the narrow band outputs, and these are used when sensitivity without high resolution is required. The amplifier has four cascaded reject circuits tuned to a frequency of 8.25 megacycles. When operating at a test frequency of 1/2, 1, or $2^1/_4$ megacycles, the local oscillator is set on its low range and tuned to 8.25 megacycles. The tunable output is normally used and the variable capacitors are set to resonate one of the output transformers at the sum of the local oscillator and testing frequencies. When testing at 5 megacycles the high range of the local oscillator is used, the oscillator being set at 16 megacycles, and either peaked or tunable peaked output is normally used. In either case the frequency

passing through the amplifier is the difference between the local oscillator and the testing frequency, namely, 11 megacycles. The output of this amplifier is connected to the upper deflecting plate of the cathode ray tube.

Marker Circuit

In order to accurately locate defects it is necessary to have time marks on the sweep. In this reflectoscope the time marks consist of square waves imposed as vertical deflections of the sweep trace. The marks are generated by the multivibrator circuit and its associated tubes V_{14} and V_{15}. The frequency of the square waves is adjustable by means of the ganged capacitors C_4 and C_5 so that one cycle of the square wave may be made to represent any distance from one inch to two feet in aluminum. Small adjustable capacitors are connected in parallel with the main capacitor to adjust the frequency range and balance of the circuit. A modified cathode follower circuit is used to isolate the multivibrator from the capacitance of the lower cathode ray tube deflection plate plus that of the connecting cable and to clip the square waves to improve their shape.

The multivibrator is synchronized with the sweep by preventing tube V_{14} from conducting and therefore making the circuit inoperative for a predetermined interval after the sweep has begun. This is accomplished by applying a negative bias from potentiometer P_5 through the tube V_{18} to the grid of tube V_{14}, preventing it from conducting. It should be noted that because of the large negative voltage in the cathode-to-ground circuit of tube V_{16}, the plate of this tube is negative with respect to ground but positive with respect to the cathode, thereby causing it to conduct current. When the gas tube V_8 fires, the negative pulse occurring at its plate is applied to the grid of tube V_{16}, driving it beyond cutoff. This action starts the multivibrator by removing the bias from tube V_{14}. The square waves may be moved along the sweep by adjusting the bias applied by potentiometer P_5.

Operation With Raw A-C Power

There are no rectifiers in this instrument since all the tubes have alternating voltage applied to each electrode that requires an operating voltage. The characteristics of the instrument which make this possible are a duty cycle which in short with respect to the period of the supply voltage and a repetition rate synchronized to the power supply frequency. Furthermore, it is relatively easy to separate the component of the plate voltage due to the alternating supply voltage from that component which is the response to the applied grid signal.

Figure 2. Reflectogram showing flaw

The length of the duty cycle depends on the length of the longest part to be tested and the velocity of waves in that part. Longitudinal supersonic waves travel in steel with a velocity of 229,000 inches per second. The velocity in most other metals is not more than 40 per cent less than the velocity in steel. The time required for a supersonic wave train to travel down a 30-foot bar of steel and reflect back to the crystal is only slightly over 1/360th second. Since there are few applications in which it would be desirable to test a piece longer than 30 feet, the instrument is at most required to operate for only one-sixth of the time interval between pulses. The remainder of the time is provided to allow the supersonic energy in the material to be absorbed.

Figure 6 shows the duty cycle symmetrically impressed on the peak of the positive alternation of the supply voltage. From this figure it may be seen that the 60-cycle supply voltage varies by only 13.4 per cent during the maximum duty cycle of the instrument. Most electronic circuits are capable of functioning normally over such a voltage change when this change is of a slow period relative to the desired signals in the circuits. When such is not the case, the problems parallel those of a direct-coupled amplifier wherein it is difficult to prevent the operating plate voltage of one tube from reaching the grid of the next without losing part of the amplified voltage or introducing instability.

The operating frequency of the circuits in the pulse generator and amplifier is so much higher than the power supply frequency that small coupling capacitors are sufficient to separate the two. Decoupling resistors and capacitors are used in the plate, screen, and grid circuits of the amplifier, but their time constants are chosen so as to maintain the proper phase relation between the 60-cycle voltages appearing at the tube electrodes.

The signal frequency of the multivibrator and flip-flop circuits is also sufficiently above that of the power supply to permit ordinary coupling capacitors to separate the two.

Voltage Regulation

The cycle of operation should start a little before the supply voltage wave has reached its peak in order that the duty cycle shall occur during the time when the supply voltage is changing by the smallest amount. This is also the time at which the vacuum tubes have their maximum transconductance and can give the largest nondistorted voltage output.

Since tube V_8 starts the cycle of events, it should fire just before the supply voltage wave has reached its peak. This tube has a linear grid-control characteristic, and if sine waves 180-degrees out of

Figure 3. Block diagram

Figure 4. Circuit diagram. Note the absence of rectifier tubes

phase were placed on its plate and grid, the tube would either not fire at all, or would fire shortly after the plate voltage became positive. The difficulty might be overcome by changing the phase of the grid voltage with respect to the plate voltage, but then the tube would become what might be termed a negative voltage regulator. This may be explained by considering what would happen if the supply voltage should be increased. The effect on the firing point of an increase in plate voltage would be negligible compared to that of the increase in grid voltage since this type of tube has a control ratio of ten to one. The grid voltage, however, is negative, and an increase in it makes the tube fire at a later point in the cycle. Therefore, unless the increase in grid voltage were so large as to prevent the tube from firing before the positive peak in plate voltage, the other tubes in the reflectoscope would be operating at not only an increased voltage caused by the transient itself, but an additional increase because of the delayed firing of the sweep thyratron. Such a condition would magnify the effect of transients.

Not only may this magnification of the effect of transients be prevented, but the normal effect of transients may be reduced by the following means. Gaseous voltage regulator tubes V_{17} and V_{18} are used to clip the voltages applied to the plate and grid bias circuits of tube V_9. The negative grid bias derived from tube V_{18} is more than sufficient to prevent the thyratron from firing. This negative voltage and the plate voltage of tube V_9 are substantially constant during the duty cycle of the instrument because of the clipping by the voltage regulator tubes. The tube V_9 is then made to conduct by applying a sine wave of the supply frequency to the grid which is in phase with the plate voltage. The point in the cycle at which the tube fires may be moved back and forth by adjusting potentiometer P_6. Since the grid signal causing the tube to fire is positive when the plate voltages of the other tubes are positive, a transient causing an increase in voltage makes the thyratron fire earlier in the cycle, which tends to correct for the increase. But this correction is not complete as severe transients cause some movement of the sweep, probably because of the following reasons: the voltage regulator tubes allow some changes in voltage, some of the power transformers do not have linear output versus input characteristics, and the decoupling networks alter the shape of the transient before it reaches the tubes. This jitter is too small to be serious in normal industrial use.

The voltage across the positive voltage regulator tube is also used as plate voltage for the "flip-flop" and multivibrator circuits to increase the stability of these circuits.

Cathode Ray Tube

The fundamental frequency of the output of the sweep amplifier tubes V_{10} and V_{11} is quite near that of the supply voltage. Part of the positive plate voltage of the first tube may be applied directly to one horizontal deflecting plate of the cathode ray tube in order to bias the spot off the screen. To keep the spot in good focus when it appears on the screen the point inside the tube midway between the deflecting plates must be at ground potential. Therefore, it is necessary to use a negative bias voltage on the other horizontal deflecting plate equal in magnitude to the positive voltage applied to the first plate. Transformers T_1 and T_2 are used to introduce voltages which are in phase opposition to the operating plate voltages of the two tubes, it being impractical to separate the sweep output and operating plate voltages by means of capacitors. The transformer for the first

Figure 5. Diagram of sweep voltage showing rapid rise and exponential decay

Figure 6. Relationship between duty cycle and 60-cycle supply voltage

tube V_{10} reduces the supply voltage appearing with the signal to one-half the value required for spot bias, while the other transformer introduces a sufficient amount of negative 60-cycle voltage not only to neutralize the positive voltage, but to provide the other half of the necessary negative bias. The transformer secondaries are shunted by resistors and capacitors to provide a low impedance path for the sweep voltage.

The cathode ray tube is itself supplied with 60-cycle voltages from a transformer through an appropriate resistance voltage divider network. By the time the spot bias voltages have fallen to the point where they are insufficient to keep the spot off the face of the tube, the electron gun voltages are so low that no spot is visible.

Advantages of Operating With A-C Power

If the tubes in the instrument were operated with several sources of direct current, several rectifiers and power supply filter networks would be required to supply the various voltages needed. The root-mean-square plate current of the tubes when operating from an a-c supply is only about one-fourth the value of the current if unidirectional voltages equal to the peak of the alternating voltages are used. Consequently, the tubes may be expected to have a much longer life than normal, or the plate current may be increased, giving more application and voltage output together with a normal tube life.

Conclusion

It has been shown that an instrument containing rather complicated electronic circuits and having a short duty cycle in relation to the idle period may be operated entirely with alternating voltages applied to the electron tubes when the duty cycle is synchronized to the alternatting voltage; that the main problem in operating circuits in such manner is to prevent the operating plate voltage of one tube from reaching the grid of the next without attenuating the desired voltage; and that this problem has been solved in most of the circuits in this reflectoscope by the use of the appropriate size of coupling capacitors between stages.

Electric Equipment for Cold Strip Reduction Mills

W. E. MILLER
MEMBER AIEE

THE COLD ROLLING of steel strip is a process that has been actively practiced now for over a half century. Fifteen years ago, the three fastest cold mills had delivery speeds of 800 feet per minute. Two of these high-speed mills of 1933 were single-stand reversing mills, and the other, a narrow width tandem mill.

Changes in mill equipment and electric equipment since 1933 have been noteworthy. Present-day reversing cold strip mills operate with delivery speeds up to approximately 2,000 feet per minute. Tandem cold strip mills recently placed in operation in the Pittsburgh area have been operated at delivery speeds in excess of 5,000 feet per minute. One of the mills which has electric equipment of the type to be described in this paper has been operated successfully at speeds in excess of 6,000 feet per minute. The engineering problems encountered in the design of the electric control system for a modern high-speed tandem mill are as interesting and as intricate as those encountered in any field of engineering. Not only must the system be designed for exacting steady state operating conditions, but it must have a high speed of response for operation under transient conditions.

Types of Mills

However, before it can be shown how the engineering problems have been solved, it is necessary to have an understanding of how steel is rolled, and the problems which arise in obtaining a uniform high-quality product. Most modern cold strip reduction mills are either four-high reversing mills or four-high tandem mills. There are, of course, other types of mills, but they have rather special characteristics and will not be considered here. The reversing mill and the tandem mill each has its own respective field of application, with some degree of overlapping between fields.

In the modern arrangement of these mills, both receive metal strip of uniform width and thickness in coil form reduce the thickness or gauge a certain amount, impart certain physical qualities to the product, and deliver the product in coil form.

The reversing mill, Figure 1, consists of a single-roll stand, and a tension reel on each side of the roll stand. Both the mill rolls and the reels are motor-driven and arranged for reversible operation. To effect the required reduction, the strip is passed back and forth through the single set of rolls for the necessary number of passes, the screws being reset between passes.

The tandem or continuous mill, Figure 2, consists of from three to five roll stands and a tension reel arranged in a continuous line, so that the strip passes successively through the several roll stands, and is coiled under tension as it is delivered from the last stand.

As to field of application, the reversing mill has been considered adaptable to a relatively moderate production of several types of products, while the tandem mill, in general, has been considered to be a high production, single purpose unit. Thus it is, that tandem mills are usually designated as tin plate mills or sheet mills. However, a tin plate mill is generally laid out so that sheet can be rolled, and a sheet mill made capable of rolling tin plate with two passes through the mill. Such great changes in rolling schedules are made with a reduction in efficiency in

Figure 1. Typical reversing cold strip mill

Paper 48-22, recommended by the AIEE industrial control and mining and metal industry committees, and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted November 12, 1947; made available for printing December 5, 1947.

the use of the mill. It has been said that the reversing mill stresses flexibility, and the tandem mill production.

Both types of mills are driven by d-c motors supplied from adjustable voltage motor-generator sets. A few years ago, it was general practice on both types of mills to supply all d-c motors from a common bus, with one or more d-c generators supplying power to the bus. Speed adjustments between stands or on the reels were made by motor field control. It has been recent practice on reversing mills to supply power to the stand motor and reel motors from separate generators and not from a common bus. On most high-speed tandem mills now in service, all the d-c motors are supplied from a common bus. Adjustment of individual stand and reel speeds is by motor field control, and on some mills installed in recent years by so-called *IR* compensation line boosters in series with the stand and reel motor armature circuits. Such a scheme for a tandem mill is shown in Figure 3 An explanation of *IR* compensation and of a newer scheme including *IR* compensation, but without the series line boosters, will be given later.

Problems in Rolling Cold Strip

In tandem cold strip mills of the modern high speed type, the hot rolled strip coil is threaded into the entering end of the cold mill with the finishing end operating at speeds of 100 to 600 feet per minute. During or after the threading of the delivery tension reel, the mill may be accelerated to a top speed of from 4,000 to 5,000 feet per minute, or on mills now going into service even higher. After rolling most of the coil at top speed, the mill is decelerated to threading speed as the tail end of the strip is approached. It is the desire of the operator to have the strip "on gauge" at all times, or, failing in this, to get on gauge as soon as possible as the mill is accelerated and to stay on gauge as long as possible as the mill is decelerated.

There are several factors involving the working of the metal during rolling, and the balancing of stand motor constants which materially affect the strip gauge during periods of acceleration and deceleration. Tests have been made which demonstrate conclusively, even on a single stand mill, that the gauge will be heavier at low speeds than at high speeds, and heavier with low tensions than with high tensions, if all other factors remain constant. Just why the gauge goes heavy at low speeds is not completely understood, but electric means of control can be used to compensate for the effect in spite of the obscure cause.

If moments of inertia (motor plus mill) are properly balanced between stands, each motor will require the same per cent current for acceleration. If, in addition, the per cent rolling load on all stands is the same and if the per cent rated speed regulation and the per cent operating speed of all motors is the same, then as the mill is accelerated and decelerated, all motors will remain in speed correspondence. If a variety of products is to be rolled on a mill, the flexibility of adjustment required between stands by motor field control alone is such that all the conditions given are not satisfied. Practical limitations in motor and mill design also limit the extent to which it is possible to balance the moments of inertia.

It will generally be found that the per cent accelerating current required for a given set of conditions will increase from the first to the last stand. Thus, during periods of acceleration and deceleration, there will be a loss of speed correspondence between stands. For example,

Figure 2. Typical 5-stand tandem cold tin plate mill

Figure 3. Armature circuit connections for a 5-stand tandem tin plate mill with generators connected to a common bus and using series boosters for *IR* compensation

Dynamic braking resistors and contactors not shown. Total motor capacity 16,850 horsepower

during acceleration the last stand will tend to accelerate slower than the stand preceding it, and it can be seen that there will be a decrease in tension. When all motors are up to speed, tensions will be normal. During deceleration, the last stand will tend to slow down at a lower rate than the stand preceding it, causing an increase in tension between stands. Thus, due to normal mill inertia effects alone, the mill will tend to go from "heavy" to "on gauge" as the mill is accelerated and from "on gauge" to "light" as the mill is decelerated.

The combination of the low-speed effect and the effect of mill inertia on tension helps to explain some of the many tendencies, making it harder to get on gauge during acceleration than to keep on gauge during deceleration. As the operating speeds of mills are increased, the tonnage of material rolled during the accelerating and decelerating periods increases, and the importance of getting the mill on gauge during the early part of the accelerating period becomes more important. On new high speed tandem mills coils weighing 30,000 pounds are being used. If such a coil is 32 inches, in width and is finished to 0.0091 inch, its length will be 30,700 feet. If it takes six seconds to accelerate the mill from a threading speed of 500 feet per minute to a running speed of 5,000 feet per minute, a total of 275 feet of strip will be delivered from the mill. The same amount of strip will also be delivered during deceleration to threading speed. Reduction of the percentage of this material that is off gauge during acceleration and deceleration can be obtained by electric means through proper selection and design of mill motors and control.

Selection of Electric Equipment

Before the motors and control for a cold strip mill can be selected, certain mill data must be obtained and studied. First, it is necessary to know the type of material to be rolled and the tonnage required. Since the maximum reduction per stand is limited, the type of product more or less determines the number of mill stands. Sheet mills usually consist of three or four stands while most tin plate mills consist of five stands. Rolling schedules for the various products must be worked out and rolling speeds obtained. The selection of the motors depends directly upon the rolling schedules for which the mill is designed.

The method most commonly used to calculate the loads which will be imposed upon the driving motors of a proposed mill, when rolling a particular product at a specified rolling speed with a specified reduction in each stand, makes use of test data obtained from the operation of other mills of the same type. To make the test data generally applicable, it is reduced to the basis of energy units per unit of rolling work, and plotted against reduction in curve form. A typical curve for mild steel such as forms the great bulk of strip tonnage is shown in Figure 4. Use of the curve is demonstrated in Table I where a set of calculations for a rolling schedule is given.

Another method sometimes used in the calculation of rolling power requirements is to figure the rolling pressure by one of the methods using basic resistance to compression, and from the pressure, and the lever arm and speed, calculate the rolling power. However, when rolling power curves are available, their use is generally preferred since they are based on accurate electrical data.

A typical set of power calculations for

Figure 4. Typical power curve for cold rolling strip steel on a 5-stand tandem mill from 0.095 to 0.0091 inch thick. Mild open hearth steel

one schedule on a five-stand tandem tin plate mill is shown in Table I. A set of such calculations must be made for every schedule. Motor horsepower selection should be based on the heavier schedules. Strip speed through the mill and strip width do not seem to affect power consumption per ton of product in the usual operating range.

Motor Selection

A study of the set of rolling schedule calculations for the mill will permit the selection of motor horsepower ratings and speed range requirements for each stand. It is usual practice to plot the stand speeds for each rolling schedule. The maximum and minimum speeds required for each stand determine the speed range required of that stand motor. A plot of maximum and minimum speeds for each mill stand gives the so-called "speed cone." A typical speed cone for a five-stand

Figure 5. Typical speed cone for a 5-stand tandem tin plate mill

tandem mill is shown in Figure 5. It may be found that some infrequent schedules will require motor horsepower ratings slightly above those required by the heaviest normal schedule. Rather than increase the size of the motors and penalize the operation of the mill during acceleration and deceleration on normal schedules, it is present-day practice to provide mill stand power units with full class *B* insulation and to rate them on a 40 degrees centigrade continuous basis with forced ventilation. Such a rating will allow the machines to carry a 20 per cent overload continuously without injurious heating, and should provide the margin necessary to take care of the infrequent schedules and permit rolling some of the normal and lighter schedules at higher speeds at some future date.

The selection of the motor horsepower rating and speed range for each stand does not completely specify that motor. Actual motor speed, peak rating, and type of drive also must be given. These quantities should be selected on the basis of keeping the stored energies as low as possible and maintaining as near a balance as possible between stands. The peak rating of the motor is dependent upon the total Wk^2, since the mill must be accelerated carrying full rolling load plus the power required to accelerate the motor and the mill.

Since it is the effect of the Wk^2 on the electrical system which is of concern, Wk^2 for each stand must be obtained referred to the stand motor shaft. The Wk^2 of the stand motor shaft will be affected by three factors: motor Wk^2, gear ratio, and mill Wk^2. There are various drive arrangements which may be used. The simplest form consists of a single armature motor driving the mill through a pinion stand of 1:1 ratio. Double armature motors may also be used with this arrangement. In addition to reduction of Wk^2, additional advantages are obtained through the use of so-called twin drive motors where each roll is driven by a separate motor. Here, again, it may be necessary to use double armature motors, thus having a double armature twin drive motor consisting of four separate armatures.

Since the speed of the material increases as it goes through the various stands, it is necessary to either use higher speed motors at the finishing end or to use speed increasing gears of increasing gear ratio on the finishing stands. On low speed mills, speed decreasing gears may be used on the entering end stands. When referred to the motor shaft through speed increasing gears, the mill Wk^2 will be increased by the square of the gear ratio. Thus, although the mill external Wk^2 may be the same on every stand, the effective mill Wk^2 (referred to motor shaft) increases from the entering stand to the finishing stand. If any attempt is to be made to balance the kinetic energies, it thus becomes necessary to reduce the motor Wk^2's on the finishing end of the mill by increasing the number of armatures used. Thus, it will be found on large mills that the first stand may consist of a single armature motor driving through a 1-1 pinion stand, while the fifth stand may consist of a double armature twin drive motor with four armatures driving through speed increasing gears.

Table II shows the Wk^2 of the stand motors, the Wk^2 of the mill, and the per cent accelerating current to accelerate the motor only, and the per cent accelerating current to accelerate both motor and mill for a typical five-stand tandem mill. The per cent accelerating current, for the sake of convenience, is based upon accelerating from zero to maximum speed in ten seconds.

Table II. Wk^2 and Per Cent Accelerating Current

Five-Stand Tandem Tin Plate Mill

Stand	Total Hp	No. of Arm's.	Type of Drive	Motor Rpm	Gear Ratio	Wk^2-lb ft² at Motor Shaft × 1000 Motor	External	Total	Per Cent Amperes to Accelerate Mill and Motors*	Per Cent Amperes to Accelerate Motors Only*

SA-T—Single armature, twin drive.
DA-T—Double armature, twin drive.
*Acceleration in 10 seconds from rest to top rated speed with weak field setting on each motor.

While it has been said that the per cent accelerating current should be equal on each stand, it is evident from Table II that this has not been accomplished. The Wk^2 and the kinetic energy could be increased artificially on the stands at the entering end of the mill, but such a procedure would certainly be undesirable. A study of Table II indicates that it is impossible to materially reduce the kinetic energies of the last stands by changing the motors because the greater part of this energy is in the mill itself. For instance, to achieve any reduction on stand number 5, it would probably be necessary to go to eight armatures, each rated 500 horsepower. Such an arrangement would not only make the motors but also the control cost considerably more. Thus, it will usually be found on large mills that the per cent current to accelerate the mill and motors increases from the entering to the finishing end of the mill.

Where cold strip mills operate at very high delivery speeds, it becomes very important to keep the peripheral speed of the upper and lower working rolls the same at all times. On the finishing end of a mill rolling thin gauges, there is considerable pressure between rolls, even with no metal in the mill. With any difference in working roll diameters on a pinion driven mill, this would make the rolls grind each other and cause their surfaces to become rough. This is avoided with separate roll drives or twin drives which permit the rolls to be operated at slightly different angular speeds.

Figure 6. Armature circuit connections for a 5-stand tandem tin plate mill with individual generator for each stand and *IR* compensation included in regulating control system

Dynamic braking resistors and contactors not shown. Total motor capacity 16,850 horsepower

Generator Selection

Selection of the generators to supply d-c power to the mill motors is dependent

Figure 7. Amplidyne type voltage regulating control circuit showing ohmic drop compensation and stabilizing circuits for one stand of a 5-stand tin plate mill using an individual generator for each stand

upon both the mill motor horsepower ratings and the control scheme to be used. As the stage of the art of cold rolling has advanced, the higher and higher mill delivery speeds have raised the power requirements to the point where it is necessary to use almost as many generators on the bus as there are mill stands. It is evident that the flexibility of the tandem mill can be increased if the number of generators is equal to the number of mill stands, and the main bus is broken so that a separate generator then supplies the motor driving each stand. Adjustments between mill stands can then be made by generator voltage control as well as by motor field control. Thus, the speed range of each stand is widened at the lower end by reducing the horsepower output. In addition, the *IR* compensation function can be included in each stand generator regulating circuit, and the bothersome series boosters can be eliminated.

It has been found where large amounts of power are required that the most economical generator rating is about 4,000 kw. For the 5-stand tandem mill being considered, it can be seen from Table II, that a total of 13,000 kw of generating capacity necessitating at least four generators is required. In addition, a fair size booster generator would be required for the reel circuit. Since four large generators and one large reel booster will be required on the common bus scheme, the advantages are definitely in favor of the individual generator scheme requiring only one additional generator, but permitting the omission of all the high current *IR* compensation boosters, the purpose of which will be explained later. The generators selected are given in Table III, and are arranged into two motor generator sets.

Since it is necessary that the generators be able to handle any loads which the motors will carry, even when taking into account the 20 per cent overload capacity sometimes incorporated in the motors, the generators must also be completely insulated with class *B* materials. Both motors and generators are rated 600–750 volts direct current in order to have line currents at the lowest possible level without getting into difficulties inherent with higher voltages.

Selection of Control

The majority of the up-to-date tandem mills now in service are equipped with separate d-c motors on each stand, supplied as a group with d-c power from an individual generator, or a group of generators connected to a common bus and operating as a unit. The majority of the high-speed high-power tandem mills now going into service differ in that an individual generator supplies power to each stand motor. Armature circuit connections for the individual generator scheme are shown in Figure 6.

The choice of the basic control scheme is a matter of economics. Certainly, on a high-speed high-power mill the advantages of the individual generator scheme are many. First, the high-current series booster generators and their control are eliminated. Second, the heavily supported high-current bus is eliminated. Third, and most important, is that each generator may, if desired, be operated at a different voltage.

On a high-speed tandem mill electric gauge control during the mill accelerating and decelerating periods is a "must." Gauge control can be obtained during these periods if the mill motor speeds are changed in such a way as to automatically adjust the strip tension between stands. There are two general methods of control. The first is by automatic control of the shunt field strength of one or more of the stand motors, the method being called "tapered tension control by motor field adjustment." The second is by an independent control of motor armature voltage by an amount equal to or a part of the *IR* drop in the system, the method being called "*IR* drop compensation." In the past, where *IR* compensation has been provided, it has been general practice to use the series booster generators for this purpose. On new mills with the individual generator scheme of control, the series booster generators are eliminated and the *IR* compensation function is included in the regulating control system.

While both tapered tension control and *IR* compensation make it possible to get on gauge sooner as the mill is accelerated and to stay on gauge longer as the mill is decelerated, the "*IR* drop compen-

Figure 8. Amplidyne type regulating control circuit for tension reel on a tandem cold strip mill showing tension (current type) regulator and voltage regulator following reference set up by last mill stand

Figure 9. Block diagram for amplidyne type voltage regulator with *IR* compensation for one stand of a 5-stand tandem cold strip mill using individual generator for each stand. Schematic control circuit shown in Figure 7

sation" method is more nearly automatic than is the "tapered tension" method. With *IR* drop compensation, the motors more nearly "sense" gauge and automatically taper the tensions as needed. With tapered tension control, it is necessary that the tapered tension rheostats be set in advance. Thus it is that *IR* drop compensation seems to be the preferred method of electric gauge control in the ultra-high speed rolling of cold strip. Tapered tension control, or *IR* drop compensation, may or may not be considered necessary on lower speed mills.

The strip, after being rolled, is reeled into coils. Control must be provided which will automatically maintain constant tension in the strip as it is being reeled, and also automatically provide for the change in motor speed required by the reel build up. Since the strip will be delivered from the last mill stand at constant speed, and since it is desired to hold constant tension, a regulator is required which will give a constant horsepower characteristic. Such control can be provided by a regulating tensiometer measuring tension directly or by a current regulator maintaining constant reel motor armature current by changing the shunt field excitation of the reel motor.

The majority of the tension regulators now in service are of the current regulating type. The use of this type of tension regulator is based upon the maintenance of constant reel motor armature voltage. Thus, reel build-up must be taken care of entirely by field control. On modern high speed mills, coils must be large to make the full speed running time a reasonable period. Thus, the speed range required for reel build-up may be large and becomes a limiting factor in the design of the reel motor.

With the tensiometer type of tension regulator, automatic adjustments to hold constant tension may be made by changing both motor armature voltage and motor field excitation. Thus, where the coil build up is large and permissible speed range by field control becomes a limiting factor, the use of a tensiometer type of regulator will permit the use of a more nearly normal reel motor.

Control Circuits

The control circuit for the individual generator scheme for a single stand is shown in Figure 7. It is seen that the mill master rheostat determines the voltage on the master voltage control bus *MP*1 and *MP*2. This bus is the standard by which the voltage on every generator is controlled. By raising or lowering the voltage on this bus, it is possible to raise or lower (proportionately) the voltages of all the generators. The mill master rheostat also controls the excitation on the generator field exciter (*GFE*) which supplies all stand generators. In this way, the regulating exciters (*RE*) on each stand may operate at low voltage levels ideal for fast regulator action.

Individual voltage adjustment on each generator may be accomplished by movement of the stand master rheostat. Each stand motor speed can also be controlled by adjustment of its shunt field current. However, regardless of the settings on the stand master rheostats, the mill master rheostat will raise or lower each generator voltage proportionately.

It has already been pointed out that it is usually desirable not only to control all generator voltages so that they are proportional to the voltage on the master voltage control bus, but also to compensate for *IR* drop in all motor armature circuits. In this way, the speeds of all motors may be held closely proportional to the voltage on the master voltage bus. It can be seen in Figure 7 that the ohmic drop exciter (*OD*) receives its excitation from the voltage drop across the generator commutating field, and its output voltage may be made equal to or any fixed percentage of the motor armature circuit *IR* drop. The voltage of this amplidyne is automatically subtracted from the generator terminal voltage. Each stand regulator, through its regulating exciter (*RE*) then acts to hold essentially motor counter electromotive force which is directly proportional to motor speed.

The control circuit for a tension reel is shown in its simplified form (less stabilizing elements) in Figure 8. The system shown includes a tension regulator of the current regulating type. As already explained, this regulator acts to maintain constant reel motor armature current by changing the shunt field excitation of the reel motor. The over-all control is arranged so that the reel generator voltage is proportional to strip speed, and the reel build-up is taken care of by the reel motor field control. Reel generator voltage is, therefore, a function of both the last stand generator voltage and motor field weakening.

Selection of Circuits and Circuit Constants for Optimum Performance

In no other type of rolling mill does the performance of the electric equipment affect the quality of the product to a greater extent than in the case of the cold strip mill. The accuracy of the gauge, the ease of maneuvering, the mill tonnage, and the per cent yield all depend directly upon how well the electric drive system is co-ordinated. Not only must the system be designed to operate over an extremely wide range of steady state operating conditions, but it must be designed to have a high rate of response so that changes in operating conditions may be made quickly with all stands acting together.

Regulating circuits of the type shown in Figures 7 and 8 are also called servomechanisms. The study of such circuits has been both intensive and extensive during the past few years. Actual circuits have been tested to study transient performance in the laboratory, factory, and field. System studies have been made on differential and transient analyzers. Complete servomechanisms have also been analyzed by the frequency response methods of Nyquist and Bode.

Table III. Main Generator Ratings

Five-Stand Tandem Tin Plate Mill

Main Generator Set Number	Stand Number	Generator kw	Generator Voltage
1	1	1,500	750
1	2	3,000	750
1	3	3,000	750
2	4	3,000	750
2	5	3,200	750
2	Reel	500	750

Figure 10. Frequency response of voltage regulator with *IR* compensation for stand number 5 of tandem tin plate mill with motor operating with weak field

By correlating the data available, it is possible to analyze the systems of Figures 7 and 8 by the frequency response method, and to select the circuits and circuit constants which will give the desired system performance.

The complete amplidyne-type regulating control circuit for one stand of a five-stand tandem tin plate mill is shown in Figure 7. The control for every other stand is identical. Two small size identical transformers are used to obtain voltage rate of change signals for stabilization. The ohmic drop exciter (*OD*) is also used as an amplifier for the voltage rate of change signal fed back from the main generator (*G*). The amplidyne exciter used for this application is ideally suited for its dual purpose because of its high gain and very low time constant. The time constant of amplidyne *OD*, as shown in Figure 7, is less than 1/300 of the time constant of the main generator.

The block diagram for the regulating system of Figure 7 is shown in Figure 9. In constructing the diagram, it was assumed that the error introduced by considering the generator voltage feedback signal to be proportional to the rate of change of internal voltage instead of terminal voltage is small.

The basic method of analysis and the mathematical justification of the frequency response method of analysis have been completely presented in available published literature. Briefly, it is necessary to apply an alternating input signal of constant magnitude and varying frequency to the input side of the system and to determine both the magnitude of the output signal and its phase relation with the input signal. The frequency response must be determined over the whole frequency spectrum of the system. To do this mathematically, it is usual practice to break the system up into its component parts as shown in Figure 9, and to determine the transfer function of each part. These transfer functions are then combined either mathematically or graphically to obtain the system transfer function and the system frequency response. From a study of the frequency response and phase characteristics of the system components and the whole system, it is possible to select and adjust circuits so as to cause the system to have the desired transient characteristics.

Frequency response curves for the system of Figure 7 are shown in Figure 10. It is seen that the effect of *IR* compensation is to increase the peak response of the system. However, with 75 per cent compensation the peak is well within the limits recognized as required for good performance. Tests have been made and reported upon before the Association of Iron and Steel Engineers upon the advantages and disadvantages of *IR* compensation. A study of the results of these tests indicates that 75 per cent *IR* compensation is about the maximum amount which can be used to advantage on a system made up of present day mill type motors and generators.

Recent Tandem Cold Strip Mill Installations

There are five tandem cold strip mills now in service or soon to go into service which have electric equipment and individual generator control systems of the type described in this paper. Control systems on all five mills were designed using the frequency response method of determining transient performance. Initial results have been gratifying in that the regulating systems have performed as predicted. The first mill was placed in service in the Pittsburgh area in October 1947, and it is expected that the fifth mill will be rolling steel in the Chicago area during the early summer.

Mill operating and maintenance men are well satisfied with the individual generator scheme of control for tandem mills. Increased flexibility in setting up rolling schedules through adjustment of stand generator voltage, elimination of the high current series *IR* compensation boosters and reduction of the current capacity of d-c buses are factors of such importance on the modern high-speed high-power tandem mills that it is felt that all future installations will be of this type. Amplidyne type regulators designed for fast transient performance, in accordance with the latest circuit theory and extensive tests, promises to be the tool which will hold the stands together to form a finely co-ordinated mill capable of rolling a high quality steel product.

Discussion

A. F. Kenyon (Westinghouse Electric Corporation, East Pittsburgh, Pa.): In Table II of the paper, the Wk^2 values are given as referred to the motor shaft. Studies of the drives for a proposed mill often include comparisons of direct-connected motors running at the mill speed with geared motors with either a step-up or step-down ratio between the motor and the mill, and we have found that referring all Wk^2 values to the mill working rolls affords a more direct comparison of the several alternate drive arrangements.

We have compared the Wk^2 values given in Table II with the corresponding inertias of a similar 42-inch five-stand tandem tinplate mill put into operation in May 1947, this mill having 17,550 horsepower total capacity of mill and reel motors, and 5,000 feet per minute maximum rolling speed. By coincidence, the total Wk^2 of the number 4 and 5 stands of the two mills are almost identical. In the mill described by Miller, the number 5 stand is driven by a

4,000 horsepower twin-motor in which each 2,000 horsepower motor is a double armature unit. The double armature construction achieves minimum motor Wk^2, however, the two motors are arranged side by side, requiring relatively large center-to-center distance and hence relatively large Wk^2 of the step-up gearing. In the mill of which we speak, the number 5 stand is driven by a 4,500 horsepower twin-motor in which each 2,250 horsepower motor is a single armature machine. The simpler single armature construction of course results in larger motor Wk^2; however, the two motors are axially displaced so that the shaft of one motor extends over the frame of the other motor, with resultant smaller gear center distance and Wk^2. Thus, it so worked out that the total Wk^2 of the two arrangements were almost identical.

From Table II, it is noted that on the number 5 stand, the motor armatures constitute only 16 per cent of the total Wk^2. Also, it is noted that on the basis of the 4,000 horsepower motor rating, the torque required to accelerate to maximum speed in ten seconds is over 100 per cent of the motor full load torque. This is much higher than on the other stands, and a much better overall balance can be achieved by making the number 5 motor of larger horsepower capacity than is indicated by the calculated steady-state rolling loads. For instance, making the number 5 drive 4,500 horsepower instead of 4,000 horsepower, (as was done on the mill to which we have referred) may increase the motor Wk^2 by perhaps $7^1/_2$ per cent, but increases the total Wk^2 and hence accelerating torque by only $1^1/_2$ per cent, while making available $12^1/_2$ per cent greater motor output torque. Assuming that the rolling load is 4,000 horsepower in either case, the combined rolling and accelerating load with the 4,000 horsepower drive is 201 per cent of the motor full load rating, while with the 4,500 horsepower drive it is only 180 per cent of the motor full load rating.

A Study of A-C Arc Behavior Near Current Zero by Means of Mathematical Models

T. E. BROWNE, JR.
MEMBER AIEE

Synopsis: The differential equations of two idealized models of the arc column proposed by previous writers have been combined into a composite model whose behavior approximates that of actual a-c power arcs in circuit breakers and fuses near a critical current zero for arc extinction. An extensive series of curves are presented showing, for this model, the variation with time just before and after current zero of arc resistance, arc current, arc power, and dielectric strength of the arc space under certain simplifying assumptions for three different forms of circuit recovery voltage. These quantities are expressed in terms of prior arc current and voltage and of a characteristic "time constant" which depends upon the physical conditions imposed upon the arc. The model curves are compared with oscillographic measurements. The usefulness of such models in aiding the understanding of arc behavior in circuit interrupters and in correlating and making extrapolations from interrupting data is pointed out.

IN SCIENCE and engineering, calculations are generally made on the basis of precise theoretical pictures, or "models," which are only approximations to the actual physical phenomena represented. As knowledge of phenomena grows, rough simple pictures give way to more faithful and usually more complex pictures. Until recently, there have been available no pictures of dynamic electric arcs of sufficient clarity and precision to permit their use as theoretical models for more than rudimentary calculations. A common and useful approximation, or over-simplification, in dealing with a-c arcs in circuit interrupters has been to ignore the arc's resistance up to, and its conductance just after, a critical current zero for arc extinction. This has led to the expression, "currentless pause" or "current-zero period" which, while pertinent to some low-current or low-voltage cases, may be seriously inaccurate and misleading when dealing with short-circuit arcs in high-power circuits. The necessity for considering the arc column as a rapidly changing but always finite conductor was pointed out some years ago by Slepian,[1,2] who portrayed the extinction or reignition of a conducting arc column graphically but did not then attempt to make any precise calculations. This concept of the finite arc interacting with its connected circuit has been used by Cassie[3] in deriving a simple criterion for "circuit severity" which yields striking results in correlating interrupting data obtained with air-blast circuit breakers. This correlation is confirmed by unpublished results obtained at the Westinghouse High Voltage Laboratory as well as by those in Cassie's paper. The practical possibilities, illustrated by Cassie's work, of such a mathematical attack upon the a-c arc extinction problem are so attractive that a preliminary and comparatively elementary exploration of the mathematical approach to dynamic arc behavior has seemed to the author to be desirable.

Paper 48-23, recommended by the AIEE switchgear committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted November 5, 1947; made available for printing December 3, 1947.

T. E. BROWNE, JR., is research engineer with the Westinghouse Electric Corporation, East Pittsburgh, Pa.

The author wishes to acknowledge helpful constructive criticism by Doctor Joseph Slepian (F '27) and Doctor W. M. Leeds (M '45) during the preparation of this paper.

Choice and Description of Arc Models to Be Employed

General

Space limitation prevents a complete treatment here of the whole problem of arc behavior in any circuit. In the most usual practical case, however, a circuit breaker arc serves most of the time as a relatively good conductor in a circuit whose impedance is high compared with the arc resistance (the arc voltage is low compared with the circuit voltage), and in which, therefore, the current is determined almost exclusively by the circuit. In the vicinity of a normal current zero, however, the arc resistance may become so high as to reverse the situation so that the circuit becomes the principal regulator not of the arc current but of the arc voltage. The calculations of this paper will be directed particularly toward this latter high-arc-resistance situation which may lead either to "arc extinction" (complete loss of arc conductance) or to "arc reignition" (return of relatively high arc conductance). The transition situation in which the arc current and voltage are determined jointly by the circuit and by the arc, though often of much importance and thus worthy of further treatment, will be considered in the present study to be of vanishingly small duration and coincident with the passage of the current through zero. This and other idealizations, made for the sake of simple mathematical treatment, still permit, however, the derivation by means of mathematical models of a number of interesting and useful relations describing the dynamic behavior in its circuit of an arc of measurable conductance.

To represent properly the known behavior of the dynamic arc, an arc model equation should be of the general form:

$$\frac{i}{e}=\frac{1}{R}=f(W, N, t), \qquad (1)$$

where

i = instantaneous arc current
e = instantaneous arc voltage gradient

R = instantaneous arc resistance per unit length $= e/i$

W = power input to the arc per unit length $= ei$

N = power loss from the arc per unit length

t = time

or in words, the arc's conductance must be a function of the arc power input and power loss and of time—the time being necessary to account for the lag in conductance which characterizes dynamic arc behavior. In arriving at working equations for the arc, recent investigators[3,4,5] have further assumed that

$$\frac{1}{R} = F(Q) = F\left[\int (W-N)dt\right] \tag{2}$$

where Q, the energy content per unit length of the arc associated with its elevated temperature and state of ionization, is, as indicated, a result of the arc's past history. A convenient general form for the differential equation of the model arc based upon this assumption may be obtained by differentiating equation 2 and then dividing by it to give

$$R\frac{d}{dt}\left(\frac{1}{R}\right) = \frac{F'(Q)}{F(Q)}\frac{dQ}{dt} = \frac{F'(Q)}{F(Q)}(W-N) \tag{3}$$

or, in terms of e and i,

$$\frac{1}{i}\frac{di}{dt} - \frac{1}{e}\frac{de}{dt} = \frac{F'(Q)}{F(Q)}(ei-N) \tag{4}$$

The specific form of this differential equation will depend only upon the particular forms selected for $F(Q)$ and N.

Two different equations of this type based on rather different concepts of the physical nature of the arc column have been used. Mayr,[4,5] following a rather involved derivation based upon the assumption of thermal ionization according to the *Saha* equation and of heat loss by thermal conduction alone, has arrived at the forms

$$\frac{1}{R} = F(Q) = K\epsilon\frac{Q}{Q_o} \tag{5}$$

and

$$N = N_o \text{ (a constant)} \tag{6}$$

This, of course, means that the "static characteristic" of his arc is

$$ei = N_o \tag{7}$$

a rectangular hyperbola, and that the dynamic behavior of the arc is governed by a characteristic energy quantity, Q_o. The loss or gain of this energy quantity, Q_o, changes the arc's conductance by the factor ϵ (2.718). Mayr pictures the arc as occupying a cylindrical space of constant radius within which the temperature varies with both the radial dimension and time. Substitution of equations 5

Figure 1. Arc resistance versus time from Mayr's dynamic arc equation for linear current change through zero ($I = I_1\omega t$)

R_o = actual arc resistance at current zero

R_{sm} = arc resistance at current zero for cyclic steady state (Mayr)

$$= \frac{E_p}{\Omega I_1(\omega\theta)^2}$$

E_p = arc voltage at current peak

$$\left(i = I_1 t, \frac{di}{dt} = 0\right)$$

θ = time constant of arc column

and 6 in equation 4 yields Mayr's differential equation,

$$\frac{1}{i}\frac{di}{dt} - \frac{1}{e}\frac{de}{dt} = \frac{ei-N_o}{Q_o} \tag{8}$$

Consideration of this equation in combination with that of the connected circuit, as done by Mayr, yields results which are of much interest but which, as stated, are beyond the scope of this paper.

Cassie,[3] apparently in view of the studies of an arc in an air blast by Kirschstein and Koppelmann,[6] assumes an arc column within which the temperature is fixed and uniform in space and time, having

1. Constant per-unit-volume resistivity, μ.
2. Constant per-unit-volume power loss, λ.
3. Constant per-unit-volume energy content, c.
4. A cross-section area, A, varying with current and time according to the constraints 1, 2 and 3, which require that in the steady state the current density and voltage gradient also be constant, giving a static characteristic,

$$e = \sqrt{\mu\lambda} = E_o, \tag{9}$$

independent of the current. These assumptions lead to

$$\frac{1}{R} = F(Q) = \frac{A}{\mu} = \frac{Q}{\mu c} \tag{10}$$

and

$$N = A\lambda = \frac{\lambda Q}{c} \tag{11}$$

which, when substituted in equation 4, give the differential equation

$$\frac{1}{i}\frac{di}{dt} - \frac{1}{e}\frac{de}{dt} = \frac{\frac{e^2}{\mu} - \lambda}{c} \tag{12}$$

which Cassie combined with circuit equations to arrive at his criterion for "circuit severity."

Low Resistance Arc Regime

With the assumption for the low-resistance arc of the ideal condition previously mentioned, that is, that the circuit is an "infinitely stiff" current source, or $i = i(t)$, *Mayr's* nonlinear equation 8 expressed in terms of R, becomes the linear equation,

$$\frac{d}{dt}\left(\frac{1}{R}\right) + \frac{N_o}{Q_o}\frac{1}{R} = \frac{1}{Q_o}i^2(t), \tag{13}$$

with the solution:

$$\frac{1}{R} = \epsilon^{-t/\theta}\left[\frac{1}{R_o} + \frac{1}{N_o\theta}\int_0^t i^2(t)\epsilon^{t/\theta}dt\right], \tag{14}$$

where the important quantity,

$$\theta = \frac{Q_o}{N_o},$$

Figure 2. Arc voltage versus time from Mayr's dynamic arc equation for linear current change through zero

Symbols defined under Figure 1

Figure 3. Arc resistance versus time from Cassie's dynamic arc equation for linear current change through zero

R_{sc} = arc resistance at current zero for cyclic "steady state" (Cassie)

$$= \frac{\sqrt{2}E_a}{I_{1\omega\theta}}$$

E_a = arc voltage for $\frac{di}{dt} = 0$

will hereafter be called the "time constant" of the arc and R_o is the value of R at $t = 0$.

For the region of interest, closely embracing current zero, the sinusoidal arc current of peak value, I_1, and angular frequency, ω, can be expressed with sufficient accuracy:

$$i(t) = I_{1\omega t} \left(\text{for } \omega t \ll \frac{\pi}{2}\right) \tag{15}$$

Substituted in equation 14, this gives

$$\frac{1}{R} = \frac{1}{R_{sm}}\left[1 - \frac{t}{\theta} + \frac{1}{2}\left(\frac{t}{\theta}\right)^2\right] + \left(\frac{1}{R_o} - \frac{1}{R_{sm}}\right)e^{-t/\theta} \tag{16}$$

where

$$R_{sm} = \frac{N_o}{2I_1^2(\omega\theta)^2} = \frac{E_p}{2I_1(\omega\theta)^2} \tag{17}$$

and E_p is the arc voltage gradient at the peak current, I_1. Inspection of equation 16 shows that any value of R_o different from R_{sm} will simply add an exponentially decaying transient to the nonexponential term. Therefore, the form of equation 16 for $R_o = R_{sm}$ will be called the dynamic steady state form of the equation. It can also be shown to correspond to the steadily alternating form of the solution of equation 14 for a sinusoidal current in the usual case where $\omega\theta \ll 1$. This steady-state form of equation 16 is plotted as the solid line in Figure 1. The corresponding arc voltage gradient,

$$e = Ri = \frac{E_p}{2\omega\theta} \cdot \frac{\frac{t}{\theta}}{1 - \frac{t}{\theta} + \frac{1}{2}\left(\frac{t}{\theta}\right)^2} \tag{18}$$

is plotted as the solid line in Figure 2. (Since the co-ordinates are dimensionless, the curves represent either per-unit-length or total values for a uniform arc.)

Similarly, *Cassie's* dynamic arc equation becomes, for impressed current,

$$\frac{d}{dt}\left(\frac{1}{R^2}\right) + \frac{2\lambda}{c}\left(\frac{1}{R^2}\right) = \frac{2\lambda}{c} \cdot \frac{i^2(t)}{E_o^2} \tag{19}$$

with the solution,

$$\frac{1}{R^2} = e^{-\frac{2t}{\theta}}\left[\frac{1}{R_o^2} + \frac{2}{E_o^2\theta}\int_0^t i^2(t) \cdot e^{\frac{2t}{\theta}} dt\right] \tag{20}$$

where θ now represents $\frac{c}{\lambda}$, which can be shown to be equivalent to Mayr's Q_o/N_o. $\left(\text{Cassie writes his equations using "}k\text{"} = \frac{\lambda}{2c}\right)$

For

$$i(t) = I_{1\omega t}, \tag{15}$$

equation 20 becomes

$$\frac{1}{R^2} = \frac{1}{R_{sc}^2}\left[1 - 2\frac{t}{\theta} + 2\left(\frac{t}{\theta}\right)^2\right] + \left(\frac{1}{R_o^2} - \frac{1}{R_{sc}^2}\right)e^{-2t/\theta} \tag{21}$$

where

$$R_{sc} = \frac{\sqrt{2}E_o}{I_{1\omega\theta}} = \frac{E_o}{I\omega\theta} \tag{22}$$

in which $I = I_1/\sqrt{2}$ is the root mean square value of the prior current. R_{sc} is, like R_{sm}, the current-zero arc resistance for the dynamic steady state. The "steady-state" variation of Cassie's arc resistance is plotted as the solid line in Figure 3. The corresponding arc voltage gradient,

$$e = Ri = \sqrt{2}E_o \cdot \frac{\frac{t}{\theta}}{\sqrt{1 - 2\frac{t}{\theta} + 2\left(\frac{t}{\theta}\right)^2}} \tag{23}$$

is plotted as the solid line in Figure 4.

The effects of large deviations from the dynamic steady state at current zero, corresponding to the commonly observed erratic behavior of actual arcs, are shown by the dotted lines in Figures 1 to 4. Cathode-ray oscillograms of actual arc reignition voltages often resemble some one of the families of curves of Figures 2 and 4 rather closely, as for example the reignition voltages preceding the extinction transients in the oscillograms of Figure 5. Whenever the arc resistance remains relatively low, however, the resemblance, illustrated by Figure 5*a*, is noticeably closer to Cassie's form of Figure 4 than to Mayr's form of Figure 2. Furthermore, quantitative agreement, to be discussed under the section entitled Comparison with Experiment, between calculated values of R_o and those indicated by oscillograms clearly indicates Cassie's model of the low-resistance arc as the only appropriate model for representing the pre-current-zero regime for ordinary power arcs. The near-constant arc voltage gradient of Cassie's model is also clearly in agreement with the usual magnetic oscillograms of circuit breaker tests.

High Arc Resistance Regime

Just after a critical current zero at which the arc resistance has become so high that its voltage rather than its current is principally determined by the circuit, experience shows that the actual arc, or "arc space," is characterized generally by a rapid further loss of conductivity and a rapid recovery of dielectric strength. The generally used definition of this "dielectric strength" of a still conducting gas space is that given by Slepian[1,2]: the voltage required to hold the conductance of the space constant. According to equation 2, this means the voltage required for a balance between power input and power loss, or for the equality:

$$\frac{e^2}{R} = N \tag{25}$$

Figure 4. Arc voltage versus time from Cassie's dynamic arc equation for linear current change through zero

From this, the dielectric strength of the arc space according to Slepian's criterion can be defined symbolically as

$$E_d = \sqrt{RN} \tag{26}$$

Cassie's assumptions of constant per-unit-volume resistivity, μ, and power loss, λ, immediately rule out his model for this period, since the dielectric strength per unit length of his model would be

$$E_d = \sqrt{\frac{\mu}{A} \cdot \lambda A} = E_o \tag{27}$$

a constant. Mayr's assumptions, however, lead to

$$E_d = \sqrt{RN_o} \tag{28}$$

a dielectric strength increasing with the square root of the arc resistance, a relation which is at least not contrary to experience. For the high arc-resistance case of circuit-controlled voltage, $e = e(t)$, Mayr's differential equation becomes:

$$\frac{dR}{dt} - \frac{N_o}{Q_o} R = -\frac{1}{Q_o} e^2(t) \tag{29}$$

with the general solution,

$$R = e^{\frac{t}{\theta}} \left[R_o - \frac{1}{N_o \theta} \int_0^t e^2(t) \cdot e^{-\frac{t}{\theta}} dt \right] \tag{30}$$

where, as before, $R_o = R$ at $t = O$ and $\theta = \frac{Q_o}{N_o}$.

In the absence of restored voltage, or

Figure 5. Cathode-ray oscillograms of arc voltage near current zero for interruption of 3,600 amperes in a 7,100-volt 60-cycle circuit by an arc in an orifice-type air-blast interrupter

5*a* and *b* are successive tests at 95 pounds per square inch air tank pressure

where the square of the restored voltage can be neglected, equation 30 shows that

$$R = R_o e^{t/\theta} \tag{31}$$

the arc resistance approaching infinity exponentially at a rate depending only upon R_o and θ. Slepian's dielectric strength becomes

$$E_d = \sqrt{N_o R_o} e^{t/2\theta} = E_o e^{t/2\theta} \tag{32}$$

(The identity, $E_o \equiv \sqrt{N_o R_o}$, follows from equations 27 and 28.) Clearly, equation 32 must be limited to the range where the assumptions underlying it are tenable. It may not, for instance, have any validity for arc reignitions occurring at times very much greater than θ after current zero where arc reignition takes on the aspect of ordinary sparkover. Thus, it might apply to the early rapidly rising portions of experimentally determined dielectric recovery curves[7] but not to the plateau region following the rapid recovery.

Arc Model Behavior After Current Zero With Various Forms of Restored Voltage

Constant Voltage

$e = E_1$

Equation 30 becomes

$$R = \frac{E_1^2}{N_o} + \left(R_o - \frac{E_1^2}{N_o} \right) e^{t/\theta} \tag{33}$$

or

$$R = R_o \left[\frac{E_1^2}{E_o^2} + \left(1 - \frac{E_1^2}{E_o^2} \right) e^{t/\theta} \right] \tag{34}$$

For $E_1 = E_o$, the exponential term vanishes and R remains constant at R_o. This, however, is an unstable equilibrium, since R approaches zero (the arc "reignites") for any excess of E_1 over E_o, and conversely, R approaches infinity (the arc disappears) for any E_1 less than E_o. If the value of E_1 which is critical for extinction is called E_c, equation 34 shows that for this case of constant applied voltage,

$$E_c = E_o \tag{35}$$

If the ratio of E_1 to E_c is called α, equation 34 can be conveniently written

$$R = R_o [\alpha^2 + (1 - \alpha^2) e^{t/\theta}] \tag{36}$$

From equations 36 and 28, the dielectric strength of the arc space according to Slepian's definition can immediately be written

$$E_d = E_o \sqrt{\alpha^2 + (1 - \alpha^2) e^{t/\theta}}, \tag{37}$$

reducing to equation 32 when $\alpha = O$.

The arc residual or "leakage" current is

$$i = \frac{e}{R} = \frac{\alpha E_o}{R} = \frac{E_o}{R_o} \cdot \frac{\alpha}{\alpha^2 + (1 - \alpha^2) e^{t/\theta}} \tag{38}$$

If R_o, being the result of the model variation up to current zero according to the Cassie equation, is identified with Cassie's "steady-state" value,

$$R_{sc} \equiv \frac{\sqrt{2} E_o}{I_{1\omega\theta}} \tag{22}$$

equation 38 becomes

$$i = \frac{I_{1\omega\theta}}{\sqrt{2}} \cdot \frac{\alpha}{\alpha^2 + (1 - \alpha^2) e^{t/\theta}} \tag{39}$$

expressing the residual current in terms of the amplitude and frequency of the prior current as well as the time constant, θ, of the arc's conductivity and the ratio of actual to critical applied voltage, α Specifically, it states, for instance, that for exactly the critical value of restored voltage ($\alpha = 1$), the arc current will remain constant at $\omega\theta$ times the rms value of the prior arc current.

Likewise, the power input to the arc space can be written:

$$W = ei = \frac{E_o I_{1\omega\theta}}{\sqrt{2}} \cdot \frac{\alpha^2}{\alpha^2 + (1 - \alpha^2) e^{t/\theta}} \tag{40}$$

All of these quantities are plotted in dimensionless form in Figure 6 for values for the parameter α: 0, 0.707, 1.0, 1.01, 1.1, and 1.414, showing, for this composite model, the variation of these quantities with time after current zero at zero, critical and near-critical values of a constant restored voltage. The short section of curve to the left of the origin in each case represents, for comparison, the assumed model variation just before current zero, calculated according to Cassie's equation with impressed linear current fall.

Constant Rate of Rise

$e = E_1 \nu t = \alpha E_c \nu t$

In a manner similar to that used in the preceding section, it can be shown by means of equation 30 that E_c, the critical value of the voltage amplitude E_1 for arc extinction (determining the boundary between ultimate approach of the arc resistance to zero or to infinity), is

$$E_c = \frac{E_o}{\sqrt{2}\, \nu\theta}, \tag{42}$$

or that the critical rate of rise of voltage is

$$E_c \nu = \frac{E_1}{\sqrt{2}\, \theta}. \tag{43}$$

In terms of

$$\alpha = \frac{E_1}{E_c} = \frac{E_1 \nu}{E_c \nu},$$

Figure 6a—Resistance versus time
R_o = resistance at current zero = R_{sc}
θ = time constant of arc column

Figure 6b—Dielectric strength versus time

E_o = arc voltage for $\frac{di}{dt}=0$ in preceding half-cycle

Figure 6. Behavior of composite arc model with constant restored voltage,

$e = E_1 = \alpha E_c$

where E_c is the critical value of restored voltage for arc extinction

Figure 6c—Current i and power input W versus time

$I_{1\omega}$ = rate of current fall just before current zero

the ratio here of actual to critical rate of voltage rise, the arc resistance equation from 30 is

$$\frac{R}{R_o}=\alpha^2\left[1+\frac{t}{\theta}+\frac{1}{2}\left(\frac{t}{\theta}\right)^2\right]+(1-\alpha^2)e^{t/\theta} \qquad (44)$$

and the dielectric strength is

$$E_d=E_o\sqrt{\alpha^2\left[1+\frac{t}{\theta}+\frac{1}{2}\left(\frac{t}{\theta}\right)^2\right]+(1-\alpha^2)e^{t/\theta}} \qquad (45)$$

Likewise, the arc "leakage" current is

$$i=\frac{e}{R}=\frac{\alpha I_{1\omega}\theta}{2}\cdot\frac{\frac{t}{\theta}}{\alpha^2\left[1+\frac{t}{\theta}+\frac{1}{2}\left(\frac{t}{\theta}\right)^2\right]+(1-\alpha^2)e^{t/\theta}} \qquad (46)$$

and the arc power input per unit length is

$$W=ei=\frac{\alpha^2E_oI_{1\omega}\omega\theta}{2\sqrt{2}}\cdot\frac{\left(\frac{t}{\theta}\right)^2}{\alpha^2\left[1+\frac{t}{\theta}+\frac{1}{2}\left(\frac{t}{\theta}\right)^2\right]+(1-\alpha^2)e^{t/\theta}} \qquad (47)$$

These relations are plotted in Figure 7 with values of the ratio α of 0, 0.707, 1, 1.1, and 1.414. In Figure 7*b* the applied voltage rise line is drawn dotted for the critical case, $\alpha=1$, illustrating how the dielectric recovery curve for $\alpha=1$ lies almost parallel with the applied voltage line, approaching it asymptotically at infinity. Sections of the applied voltage lines for $\alpha=1.1$ and $\alpha=1.414$ are shown intersecting the corresponding dielectric recovery curves at their peaks where, as called for by the definition, the rate of change of arc resistance and therefore of dielectric strength is zero. When the applied voltage exceeds the dielectric strength, the latter soon collapses to zero (assuming the circuit to be an infinitely stiff voltage source). With finite circuits this collapse would, of course, mark the return of the "low resistance regime" where current rather than voltage is determined by the circuit.

Figure 7*c* shows the computed effect of the varying arc resistance on the course of the current with the various rates of rise of restored voltage. At critical and just below critical rates of rise the model residual currents rise to a peak of a few tenths of the prior arc current peak times $\omega\theta$ at a time close to θ and then decay to zero in an exponential manner. At greater than critical rates of rise the current merely experiences a more or less sharp deviation in slope for a time of the order of θ before suddenly rising toward infinity (approaching the undeviated current line with a finite circuit).

The model power input curves of Figure 7*d* emphasize the importance of α in determining the energy balance of the arc. At rates of rise less than 70 per cent of critical, the power input to the arc remains so far short of the assumed steady loss that the arc's loss of conductivity and its dielectric recovery are little different from what they would be with no restored voltage, as can be observed in Figures 7*a* and 7*b*. On the other hand, an early and sharp upturn characterizes the power curves for rates of voltage rise only slightly in excess of critical. For a finite circuit, of course, the power curves for arc reignition would necessarily reach a maximum and then fall to or near the power loss level upon a return to the circuit-limited-current or low-arc-resistance regime.

In Figure 7*e* are plotted, along with the static characteristic, the dynamic volt-ampere characteristics corresponding to the various values of α for the linear voltage rise case. Time is expressed as a parameter indicated by the location along the curves of the numbered dots. Such plots, with a little interpretation, can give a very complete picture of the arc behavior near current zero and are especially instructive when compared with the static characteristic.

The latter can be plotted from a family of reignition volt-ampere

Figure 7a—Resistance versus time

Time shown as a parameter by spacing of dots for integral values of t/θ

Figure 7 (a,b,c,d,e). Behavior of composite arc model with constant rates of voltage rise (approximation to the case of the resistance shunted arc)

α = ratio of actual to critical rate of voltage rise for arc extinction

curves at various rates of voltage rise by connecting in a smooth curve points at which the dynamic curves have tangents passing through the origin. The arc resistances are given by the slopes of lines from any point to the origin, dielectric strengths are the voltages at the intersections of these lines through the origin with the static characteristic, and power inputs are the products of the point co-ordinates. The common slope with which all the dynamic curves pass through the origin is, of course, R_o, the initial arc resistance. Such plots, traced out by a single cathode-ray oscillograph beam provided with timing markers, thus offer attractive possibilities for studying the near-current-zero behavior of actual arcs.

Square Law Rate of Rise

$$e = \frac{E_1}{2}(\nu t)^2 \tag{48}$$

For a complete mathematical description of the restored voltage with actual circuits, much more complex expressions than those of the preceding sections are required. Better approximations for certain still idealized cases are as follows: In a purely resistive circuit where the initial ($t=0$) current and voltage are assumed to be zero,

$$e = E_1 \sin(\nu t), \tag{49}$$

where ν is the angular frequency ($2\pi f$) of the supply generator and so is the same as ω for the prior arc current. In a purely inductive circuit with pure resistance r shunting the arc,

$$e = E_1(1 - \epsilon^{-\nu t}) \tag{50}$$

where

$$\nu = \frac{r}{L},$$

the reciprocal of the circuit time constant, is large compared with the generator angular frequency, ω. At small values of νt, both of these forms can be approximated by the linear rise expression of the preceding section. However, for the arc in a purely inductive circuit shunted by capacitance, the idealized voltage recovery is given by

$$e = E_1[1 - \cos(\nu t)], \tag{51}$$

having a zero initial rate of recovery. Equation 48 of this part is the short-time approximation for this form.

Figure 8e (right)—Voltage versus current

Figure 8. Behavior of composite arc model with voltage rising as the square of the time (approximation to the idealized case of the capacitance shunted arc)

α = ratio of actual to critical amplitude of voltage rise for arc extinction

Carrying out the integration of equation 30 for this case shows that the critical amplitude,

$$E_c = \frac{1}{2}\sqrt{\frac{2}{3}}\cdot\frac{E_0}{(\theta\nu)^2} \tag{52}$$

and that the arc resistance equation is

$$\frac{R}{R_0} = \alpha^2\left[1+\frac{t}{\theta}+\frac{1}{2}\left(\frac{t}{\theta}\right)^2+\frac{1}{6}\left(\frac{t}{\theta}\right)^3+\frac{1}{24}\left(\frac{t}{\theta}\right)^4\right]+(1-\alpha^2)\epsilon^{t/\theta} \tag{53}$$

where, as before, E_c is the critical value of E_1 for arc extinction and α is the ratio of E_1 to E_c. From equation 53, the equations for dielectric strength, current, and power input can be derived as before. Figure 8 is a plot of all these relations for this case with the same values of α as in Figure 7.

Again, the curves in Figure 8*b* illustrate the parallelism of the voltage and dielectric strength curves for the critical case (α = 1) and the divergence or convergence of these curves for α less than or greater than one, respectively. Figure 9, which is a replot from Figure 7*e* and 8*e* to a common and extended scale, shows the comparative behavior of the model arc under critical conditions with the resistance and with the capacitance-shunted types of early voltage recovery. It also shows more clearly than before the relation between these dynamic characteristics and the assumed static characteristics for the model, both before and after current zero.

Sine Law Voltage Rise

$$e = E_1 \sin(\nu t) \tag{49}$$

The integration of equation 30 for this form has already been shown by Mayr[4] to yield an

$$E_c = E_c\sqrt{2+\frac{1}{2(\theta\nu)^2}} \tag{54}$$

and an arc resistance equation

$$\frac{R}{R_0} = \alpha^2\left[1+\frac{2\theta\nu\sin(2\nu t)-\cos(2\nu t)}{1+(2\theta\nu)^2}\right]+(1-\alpha^2)\epsilon^{t/\theta} \tag{55}$$

with the other pertinent relations derivable in a straightforward manner. The arc model behavior can be seen to be a function not only of t/θ and α but of a new parameter, $\theta\nu$, making its graphical representation more complex. For this reason, and also because at the longer times, when this and the following voltage rise equations are needed, the effects of departures from the assumed conditions would be cumulative, the relations for this and the following cases have not been plotted.

A significant deduction from equations 54 and 55 is that at very high frequencies ($2\theta\nu \gg 1$) the response of the model arc

resistance to an alternating restored voltage is the same as to direct voltage of the same effective value, a fact easily deduced also from physical considerations for any arc model incorporating a time lag.

Exponential Voltage Rise

$$e = E_0(1 - \epsilon^{-\nu t}) \tag{50}$$

For this case, Mayr's computations lead to:

$$E_c = E_o\sqrt{1 + \frac{3}{2\theta\nu} + \frac{1}{2(\theta\nu)^2}} \tag{56}$$

and

$$\frac{R}{R_o} = \alpha^2\left(\frac{E_c}{E_o}\right)^2\left[1 - \frac{2}{1+\theta\nu}\epsilon^{-\nu t} + \frac{1}{1+2\theta\nu}\epsilon^{-\left(\nu + \frac{1}{\theta}\right)t}\right] + (1-\alpha^2)\epsilon^{t/\theta} \tag{57}$$

with the other relations following as before. It can be easily shown that these equations become the same as for the section entitled Constant Rate of Rise at small rates of rise ($\theta\nu \ll 1$) and the same as for the section entitled Constant Voltage at high rates of rise ($\theta\nu \gg 1$).

Oscillatory Voltage Rise

$$e = E_0[1 - \cos(\nu t)] \tag{51}$$

Mayr's solution for this case leads to:

$$E_c = E_o\sqrt{\frac{2}{3}\left[1 + \frac{5}{4(\theta\nu)^2} + \frac{1}{4(\theta\nu)^4}\right]} \tag{58}$$

and

$$\frac{R}{R_o} = \frac{\alpha^2}{2}\left(\frac{E_c}{E_o}\right)^2\left[3 + 4\frac{\theta\nu\sin(\nu t) - \cos(\nu t)}{1+(\theta\nu)^2} - \frac{2\theta\nu\sin(2\nu t) - \cos(2\nu t)}{1+(2\theta\nu)^2}\right] + (1-\alpha^2)\epsilon^{t/\theta} \tag{59}$$

from which the corresponding relations for dielectric strength, current, and power input can be deduced. Again, it can be shown that the resistance equation 59 reduces to that for the section entitled Square Law Rate of Rise at short enough times ($\nu t \ll \pi/2$ and $t/\theta \ll 1$) and to that for the section entitled Constant Voltage for high enough frequencies ($\theta\nu \gg 1$).

Comparison With Experiment

Low Arc Resistance Regime

The arc voltage reversal, or "reignition transient," preceding the final, or "extinction transient," in Figure 5*a* can be used as a rough quantitative check of the chosen arc model behavior under the continuing condition of relatively low arc resistance. From Figure 4, the re-established voltage peak should occur near

ance than predicted by the model. This difference in timing between the model and actual arcs can easily account for discrepancies of as much as ten to one, for example, between observed and predicted values of arc resistance at current zero. Because of the relation, $E_a = \sqrt{R\ N}$, corresponding discrepancies in dielectric strength may be only three to one. Studies of these discrepancies between the theoretical model and actual arc behavior should aid greatly in achieving a better understanding of actual arc processes.

Discussion

Since this study concerns the arc column alone, it cannot, of course, be applied to short-arc switches such as low-voltage relays and contactors or metal plate "De-ion" air circuit breakers. It may be applied to interrupters employing long arcs, where the characteristics of the arc column predominate. These include all gas-blast and magnetic-blast circuit breakers—not excepting those employing liquid or solid gas evolving media—expulsion fuses and protective gaps, and long power arcs in the open air. The study is generally of interest only in the higher ranges of current where the arc does not completely "go out," or lose its conductance, before a current zero.

Of greatest practical interest are the curves of Figure 7 for constant rates of rise of recovery voltage. Examination of cathode-ray oscillograms like those of Figure 5 shows that, even when the restored voltage is oscillatory, passage of the voltage through zero may be approximately linear. The square-law type of voltage rise of Figure 8 is approached only with comparatively large values of shunting capacitance. (Illustrated by Figure 4*d* of Reference 7.)

As an example of a possible use of these curves and equations, oscillographic data such as that of either Figure 5 or Figure 11, permitting an estimate of θ for a particular arc condition, may be used, along with the usual test data from magnetic oscillograms, to construct a complete model of the arc for use as a starting point for quantitative estimates. For instance, a critical rate of voltage rise for arc extinction may be computed from equation 43,

$$\left.\frac{de}{dt}\right|_c = E_a\nu = \frac{E_a}{\sqrt{2}\theta}$$

or the current-zero arc resistance for comparison with the required value for critically damping circuit oscillations may be estimated by means of equation 22,

$$R_{ac} = \frac{E_a}{I\omega\theta}$$

Figure 10. Power flow in composite arc model with linear passage of current through zero

$(i = I_{1\omega}t)$

Figure 11. Replots of cathode-ray oscillograms of arc current magnitude versus time near current zero for actual interruption tests

Figure 11*b*—Interruption of 507 amperes in 4 half-cycles in a 0.625-inch by 4-inch boric acid fuse tube, 1,680-volt circuit, $E_a = 330$ volts

Such computations are aided by the tendency in many cases for θ to remain about the same for a given arc arrangement, even though such conditions as gas pressure[2] may undergo wide variation. Theoretical calculations of θ, based on the defining relations,

$$\theta = \frac{Q_o}{N_o} \text{ or } \theta = \frac{c}{\lambda}$$

are possible but the practical reliability of such calculations has not yet been demonstrated.

Being based on generally similar premises, the dielectric recovery equations and curves for small energy input ($\alpha \ll 1$) resemble closely those predicted earlier by Slepian[1,2] from the assumption of conductivity loss by diffusion of ions. Therefore, deductions with regard to practical devices made then are still applicable. The assumption of equation 2, that arc conductance is a function of energy content alone, reduces the generality of these calculations compared to those of Slepian but available checks with observed dynamic arc behavior seem to justify this assumption for practical purposes. It should be noted, of course, that the model equations do not actually depend on any specific mechanisms of gain or loss of energy and conductivity but only on the rather general assumptions as to functional forms expressed by the equations 2, 5, 6, 10, and 11. Any natural processes which conform even approximately to these relations would explain arc behavior resembling that of the model. As an example of insensitivity to specific assumptions, it may be noted that, at zero energy input, the equations of Mayr and Cassie for rise of arc resistance (equation 31) become identical and their curves have a very similar appearance even as critical voltage recovery is approached.

The justification for speaking of a unique dielectric recovery curve under practical conditions where interrupters usually enjoy a factor of safety is clear from curves like those of Figures 7*a*, 7*b*, 8*a*, and 8*b*, which show the small effects on rise of resistance and dielectric strength of the model arc of recovery voltage amplitudes less than 70 per cent of critical. It is also shown, however, that attempts such as have been made in the past[7] to determine these dielectric recovery curves from data obtained only by near-critical tests may fail, or at least may give pessimistic results. Thus, dielectric recovery curves from critical tests with capacitance shunts may be expected to differ materially in shape and magnitude from those obtained with resistance shunts, even for the same interrupter in the same supply circuit. (Compare curves for $\alpha = 1$ in Figures 7*b* and 8*b*.)

In addition to the uses already suggested, this or similar models may also be used for the mathematically more difficult investigation of the mutual interaction between the arc and the circuit as already attempted by Cassie[9] and Mayr.[4,5] More experimental studies like those by Lewis[8] of near-current-zero arc currents and resistances in various types of interrupters under various circuit conditions are urgently needed to establish sounder bases for arc calculations; but preliminary calculations like those described here are, in turn, of value in guiding such experimental studies, which should lead to far better understanding of circuit

interruption phenomena and, as a result, to sounder design, rating, and application of circuit interrupting devices.

Discussion

Laurel J. Lewis (University of Washington, Seattle, Wash.): The study of physical phenomena by analytical methods even under idealized conditions, as in the present paper, is particularly valuable in extending our understanding of complicated relationships. It is gratifying to note the considerable advancement that has been achieved in study of arc behavior, as is evidenced by a comparison of the present "models" used for analysis and the simpler ones in use only a few years ago. It seems appropriate, however, to emphasize the limitations of measurements of external arc characteristics in determining what goes on internally in the arc space. Certainly Browne will agree that correlation between mathematical equation and test result must not be taken too literally in interpreting the mechanism of arc conductivity. For example, in those cases where the precurrent-zero variations are represented best by Cassie's equations, based on a variable radius of the positive column, and the variations following current zero are best represented by Mayr's equation based on a constant column radius and variation in temperature throughout the cross-section, it would be improper to conclude that such changes in the positive column are thereby demonstrated. We still have a long way to go in knowledge of the arc mechanism, which can only be determined by physical research under rigidly controlled conditions.

It would seem that one of the most vital questions concerning the knowledge of arc behavior centers about the conditions existing precisely at the instant of current reversal. In Figure 11*a*, the current curves all appear to be tangent at the current zero points. Perhaps Browne could indicate how accurately the zero position is known for these oscillograms. In the writer's own investigation, a significant change in slope of the current curves was sometimes noted prior to reversal, and the slopes were not the same at the zero position. A related point is whether the current and voltage zeros are coincident, since in the application of the "models," in all cases except as given under the section entitled "Arc Model Behavior After Current Zero with Various Forms of Restored Voltage," the voltage has been taken as starting at zero, coincident with the current. The evidence in the writer's study seemed to indicate some time difference in the zero values. If this is really so, the concept of "resistance" as applied to the arc space needs a different interpretation than that usually employed, inasmuch as the arc space acts as a source rather than as a sink of energy during a brief period, and the result is a discontinuity in the resistance.

It is noted that all the curves calculated by Browne for the high resistance regime applicable to interruption ($\alpha > 1$), the resistance increases approximately exponentially with time from an initial value R_e. It was again the conclusion of the writer, for the test circuit studied, that even at the last half-cycle where clearing was finally effected, there was first a period, perhaps as long as 25 microseconds, during which the ratio of arc voltage to current decreased as the current built up to a maximum, after which the "resistance" began to increase as the current decreased to zero. For cases where restrikes occurred, the ratio of voltage to current decreased continually until the normal arc was re-established. Under these conditions it seems questionable whether one should consider the dielectric strength or critical gradient in a "static" sense as being related to a voltage and a resistance at a specific instant of time. Rather the question of whether or not breakdown is to occur for a given voltage at a certain instant, is related to the resistance that existed some time previously and to the current that has been permitted to flow to furnish the energy necessary to enhance the conductivity. The situation is somewhat analogous to that in impulse testing, where the time of application of voltage is important.

W. G. Hoover (Stanford University, Stanford, Calif.): This very interesting paper is a definite contribution to the understanding of arc phenomena in circuit breakers. It helps to clarify the explanation of the influence of circuit recovery characteristics upon arcing time.

It would be of interest for the author to discuss the relative applicability of his derivations to the wide range of rated circuit breaker voltages and interrupting currents covered by present practice. As a particular question, in high-voltage high-speed, short arcing time circuit breakers, does the rapid lengthening of the arc and powerful deionizing action before current zero modify significantly the relationships developed in this paper?

W. F. Skeats (General Electric Company, Philadelphia, Pa.): The author has presented an attempt at mathematical analysis of arc properties in the neighborhood of current zero on the basis of a combination of relationships assumed by two earlier authors. It seems pertinent to point out that there are certain peculiarities in both of these sets of assumptions. Mayr, for instance, assumes an arc column whose temperature varies with time, but whose power loss is constant; while Cassie assumes a circular section with power loss throughout but no radial temperature gradient and no change in energy content per unit volume. That the change in power loss in Mayr's case, and the temperature gradient and change in energy content in Cassie's case, are negligible is possible but certainly not obvious.

The separation of the problem into one regime in which the outside circuit may be considered as controlling current with relatively little effect from arc voltage and a second in which the outside circuit controls voltage with relatively little effect from arc conductance is a useful device as long as the phenomena in question are limited to these two regimes. There is, however, an intermediate regime in which neither voltage nor current is independent of the properties of the arc and the fact that there are so many cases in which the recovery transient has been observed to be substantially affected by post-arc conductivity indicates that very often the phenomena fall within this regime. The results of any analysis avoiding this regime, therefore, are definitely limited.

This is illustrated in the author's Figures 8*b* and 8*c* in which the slopes of both current and voltage show a sharp decrease as the current passes through zero. The usual circuit will permit an increase in the voltage slope accompanied by a decrease in the current slope, or vice versa, if the properties of the arc undergo a suitable change at that time; but no circuit comes to mind, certainly not that of the idealized capacitance-shunted arc to which these curves are intended to apply, which will permit a simultaneous sharp decrease in both quantities.

The author discusses at some length the subject of dielectric strength, noting that its variation with time may be quite different for different applied voltage transients. At one point, he even utters a warning that dielectric recovery curves obtained from near critical tests may give misleading indications as to the shape of these curves under recovery voltage conditions well below the critical. Is it to be implied from this concern that it is more important to know the dielectric strength of a gap that is only lightly stressed than to know the strength of a gap stressed nearly to failure? Perhaps it would be well to consider that since the dielectric strength as defined by the author describes the response of the circuit breaker to a type of transient that rarely, if ever,

occurs in the course of circuit breaker operation, it is an item of rather academic interest. From the practical standpoint the curves for the critical value of applied voltage seem much more significant.

In view of the foregoing limitations together with those which the author himself has mentioned, it seems quite premature to suggest that the measurement of such quantities as the author has mentioned should be used for determining the limiting rate of rise at which a circuit breaker will perform satisfactorily. In spite of the difficulties associated with applying the desired rate of rise under all circumstances, it appears that that procedure will be more satisfactory and reliable for some time to come. The use of R_{86} for determination of critical damping has the further objection that even according to the author's picture it is not this resistance, but a resistance occurring substantially later, and therefore quite different, which determines damping conditions.

There is no disagreement with the author's statement of the need for more data on the performance of actual circuit breakers in this respect, and it should be emphasized that it is desirable to obtain such data on circuit breakers quite similar to those on which it is to be applied as the characteristics of different circuit breakers may be quite different in this respect.

W. M. Leeds (Westinghouse Electric Corporation, East Pittsburgh, Pa.): Circuit interrupting devices, which comprise an important class of electrical equipment, have so far defied most attempts at exact design calculation, particularly with respect to interrupting capacity. However, one noteworthy example of precalculated circuit breaker performance is in connection with the metal plate De-ion air circuit breaker for ratings as high as 25,000 volts. The theory and the structural development of this circuit breaker were described in two papers presented to the Institute in 1929 by Slepian,[1] Dickinson and Baker.[2] The fundamental principle was based on the experimental fact that a short a-c arc between metal plates requires a reignition voltage of at least 200 volts crest if the arc is to continue beyond a normal cyclic current zero. This minimum dielectric strength recovery in the gap is attributed to the positive ion space charge layer at the cathode. By splitting up a single arc into a multiplicity of short arcs between metal plates, each with its own cathode space charge layer, high voltage circuit breakers were designed successfully to interrupt at the first current zero after the arc transfer to the plate structure has taken place.

Another attempt to reduce circuit breaker design to a mathematical formula is represented by the "displacement theory" of circuit interruption. As first enunciated by Prince and Skeats[3] in 1931 in connection with an oil blast breaker, the criterion of successful circuit interruption is that the impulse strength of a fluid dielectric in volts per inch multiplied by the velocity in inches per second at which a growing film of this dielectric is introduced following a current zero shall be equal to or exceed the rate of rise of recovery voltage in volts per second appearing across the contact gap.

Circuit breaker designs built in accordance with the oil blast principle have shown greatly improved performance. However, Slepian has demonstrated in his paper[4] presented in 1940 that the idealized model presented by the displacement theory is impossible according to accepted hydrodynamical theory. Furthermore, the experimental evidence does not confirm quantitatively the predicted linear relationship between voltage recovery rate and critical fluid flow velocity. As a result, the exact mechanism by which arc reignitions are prevented has remained somewhat vague and confused, reminding one of the turbulence in the arc space which seems characteristic of the phenomena under discussion.

Back in 1933 Van Sickle and Berkey presented a paper[5] giving experimental evidence of leakage currents following current zero in high power circuit breakers obtained with cathode ray oscillograms showing definite damping action on the recovery voltage transients. Through this work and that of other researchers the evidence has been accumulating to show that post-arc conductivity and the constants of the circuit are interrelated in a definite manner, particularly when approaching the limit of arc rupturing ability.

The author is to be commended for bringing to the attention of the Institute the important analytical work of Cassie and Mayr in this field. Cassie's criterion of circuit severity, indicating a direct proportionality between the critical air pressure required by an air blast circuit breaker and the arc current multiplied by a special type of impedance function, seems to agree surprisingly well with experimental data. It is important to note that Cassie's impedance function is determined both by the circuit constants and the characteristic time constant of the arc discussed in this paper.

By means of a dual idealization of the arc column, differentiating between conditions before and after current zero, the author has obtained a mathematical formulation which appears to follow the observed behavior of an arc during the extinction process with considerable accuracy. Although most of this analysis has been applied either to only moderately effective oil interrupters or to air circuit breakers which characteristically show appreciable arc space conductance for a short time after current zero, it is expected that the fundamental principles apply equally well to the most effective oil circuit breakers with their usually more abrupt transition from conductor to insulator at current zero.

Regardless of the mathematical precision of predictions based on idealized arc models, any clarification of the basic theory underlying the interrupting process is of assistance in guiding circuit breaker design with increased reliability.

B. V. Hoard (Bonneville Power Administration, Portland, Ore.): The design of most electrical equipment is usually considered to be a science, but when the problem of interrupting an electric circuit is involved, whether by circuit breaker, fuse, or other means, knowledge of arc phenomena under various conditions is so limited that the design of this equipment is still more of an art than a science. The development of usable and illustrative mathematical expressions in Browne's paper, which indicate the probable behavior of an a-c arc near current zero under various conditions, is an important advancement in helping to understand this complicated phenomena.

This knowledge in turn should be applied to obtain better performance characteristics for fuses and circuit breakers. Electric power systems are growing rapidly, and there is need for very large circuit breakers on these systems that will have improved characteristics and reliability. For example, while circuit breakers having 10,000,000-kva interrupting rating are to be installed in the near future at the Grand Coulee power plant, exploratory studies of future system arrangements indicate that 10 to 15 years from now as more lines, loads, and generating stations are added to the system of the Bonneville Power Administration, circuit breakers having 12,500,000 to 15 million-kva interrupting rating will be required at Grand Coulee if all 18 generators are directly paralleled. It is expected that as the system grows, circuit breakers of 7,500,000 and 10,000,000-kva interrupting rating will be required at several substations, and larger circuit breakers may be required at new hydro generating stations, plans for which are now being formulated.

With such large concentrations of power and of interrupting duty on circuit breakers, it is our belief that any advancement which will make it possible to make the design of interrupting equipment more nearly a science rather than an art is well worth while. Browne's paper is an important step in this direction, and we hope that in the near future other additional steps will be taken.

A. M. Cassie, nonmember (Electrical and Allied Industries Research Association, Greenford, Middlesex, England): May I congratulate the author on a very clear and illuminating account of recent attempts to formulate the dynamic properties of the arc and to apply the results to the extinction of arcs in circuit breakers. He has himself made no mean contribution to the subject by combining the two forms of dynamic equation which have been proposed, so presenting a clear account of a problem which has proved baffling, and is still far from having been completely solved. It would appear that, until more experimental data become available, this composite representation is perhaps about as far as we can usefully go by calculation. So far the main value of these theories has been to show the type of information which is required and the lines along which further investigation ought to be carried out.

In the hope that it may prove useful, I should like to amplify a little what was said in my paper on this subject to the Paris Conference in 1939. That was, of necessity, brief to the point of obscurity in several respects, particularly in regard to the mode of application of the dynamic equation. My first attempts to set up such a dynamic equation visualized, as does Mayr, a hyperbolic static characteristic. The difficulty about such an equation, besides the purely mathematical one, is that the time constant in the dynamic equation proves to be a function of the arc diameter. Mayr has not really overcome this difficulty, and, by limiting arc losses to conduction only, precludes the static—and perhaps dynamic—characteristics which apply to the greater portion of the duration of the circuit breaker arc, where convection is the major loss process. Mayr's equation is in fact, as the author points out, limited in its application to the period, say, 10 to 100 microseconds after current zero. The consideration of the physical state of the arc column at, and immediately after, current zero, which led to the theory put forward in the Paris paper, suggested the possibility that, by assuming the steady state voltage, e_a, as nearly constant over that period, and by regarding that period as critical, it might be possible to work out a critical equilibrium state between arc and circuit. The author is, of course, perfectly correct when he points out, equation 27, that such a dynamic equation leads to a constant final dielectric strength too small for the circuit breaker to extinguish. The most striking consequence of the equation at this stage was to show that, even for an infinitely steep restriking voltage transient, in the form of a unit function, $E1$, the dielectric strength would not need to reach the value E_1 until a time comparable with a few times $1/k$ or θ after current zero. Step by step calculations of resistance and energy-time curves showed just how slow the rise in e_a need be, and encouraged the hope that the project of combining the simplified dynamic equation with those of the circuit might bear fruit.

It is here that the author's conception of the critical stage in arc extinction and that put forward in the Paris Conference part company. To make this clearer, we can think of the extinction period as divided into four parts. First there is the period when the circuit controls the current through the arc and the latter adjusts its voltage gradient accordingly; next there is the period, which the author aptly terms the "transition" period, in which the current and voltage are determined jointly by circuit and arc; in the third period the voltage across the arc is governed principally by the high frequency circuit characteristics and only slightly modified by the arc's conductivity. This is the period to which Mayr's type of equation applies. In my equation, e_a in this period would be varying at a rate comparable with the time-constant of the arc, in which case, of course, the equation would no longer be valid; lastly, there is the period when any arc-type of equation ceases to apply, and the sparkover type of phenomenon becomes appropriate.

In the Paris conference paper, the second of these periods is taken to be the critical one, at any rate for a large circuit breaker working at its limit of breaking capacity. In that period, e_a can be treated as approximately constant and interest is centered around the rising resistance very shortly after zero. It is assumed that, once the arc has gained control, the rate of energy input is no longer raised as a consequence of the *rising resistance* of the arc stream, then, in the following period, e_a will rise sufficiently rapidly to provide for the necessary dielectric strength. The author, on the other hand, regards the third period as being the critical one. I do not think there is sufficient evidence available at the moment to decide which hypothesis is the more correct. It is possible that the correct answer will require a more complete treatment of both periods together. There can be little doubt that, where smaller rms currents are in question, the analysis as applied by the author to the third period, and by Mayr to many other types of arc problem, must be the more appropriate. Deductions like the severity formula must be regarded in the meantime as derived from over-simplifications.

I would point out in conclusion, and here I think the author will agree with me, that the picture of gas blast circuit breaker operations which Mayr puts forward in his paper is not very satisfactory. It appears to be an attempt to translate the convection case into terms of a heat conduction problem, and in so doing overlooks the main factor in extinction by blast. All the experimental evidence goes to show that the extinguishing power of a circuit breaker where blast is not employed in some form or other, with the possible exception of arcs in hydrogen, is relatively insignificant. Any theory of the switchgear arc which fails to take this basic fact into consideration would appear of necessity to be incomplete. There are, none the less, possible alternative views of the function of the blast. A discussion of these, however, is too far removed from the subject of the paper to be in place here.

T. E. Browne, Jr.: In answering the several discussions, I should like to re-emphasize the statement in the introduction that this paper is merely "a preliminary and comparatively elementary exploration of the mathematical approach to dynamic arc behavior" applied particularly to the a-c arc near current zero. It seems proper and is gratifying that a number of questions have been raised about this application. As well expressed by Hoard, this is just a small step in an effort to reduce the art of circuit interrupter design to a science. Very much more needs to be done before a really complete theory usable for circuit breaker design can be evolved. Even the possibility of such a theory is still uncertain, but, as stated by Leeds, it is felt that any clarification of the basic arc theory underlying circuit interrupter design may be of assistance in the design art.

The question raised by Hoover as to the applicability of arc model calculations to a wide range of interrupted voltages and currents and interrupter types must certainly await a great deal more study for an answer. It would appear that any single simplified model would have to be used only in a relatively restricted range of these variables, a rather wide variety of models being required to cover the whole field of design. The particular model presented in the paper has possible utility, as stated, only in the higher ranges of current where appreciable arc conductance is known to persist past current zero.

The caution by Lewis against interpreting general agreement between observed arc current and voltage curves and the model curves as confirming the oversimplified physical pictures of the arc underlying the models serves to reinforce a similar caution expressed in the paper. However, the photographic studies of air-blasted a-c arcs by Kirschstein and Koppelmann[1] and of d-c arcs by Suits[3] do serve to present a picture of the actual arc prior to current zero rather similar to the simplified picture of Cassie's model. Much less is known, of course, about the physical state of the arc space during the fleeting moments at and just after a current zero.

In answer to Lewis' question about the accuracy of location of the zero in the oscillogram of Figure 11*a*, the accuracy is not high but is believed to be sufficient to locate the curves on the rather coarse-scaled plot shown. It is hoped that much more accurate and detailed information about these current transitions will be obtained with an improved amplifier now being built. It is believed that the apparent time displacements observed by Lewis[2] between arc currents and voltages resulted from predictable time lags in his measuring circuits. The interesting but surprising initial fall of the arc resistance observed by Lewis may have been due partly to this time lag but its considerable duration suggests other principal causes. It is interesting to note that for a "square wave" of applied voltage, to which several of Lewis' voltage curves are roughly similar, Figure 6*a* of the paper does show a critical-condition arc resistance, which, though not falling, is constant with respect to time. It is believed that the lack of a unique dielectric strength near critical conditions shown by the multiplicity of curves in Figures 6*b*, 7*b*, and 8*b* does illustrate the observation by Lewis that arc reignition results from energy flow over a period of time, rendering instantaneous dielectric strength of the arc space by any definition of somewhat questionable meaning. However, as pointed out in the paper, the justification for speaking of a definite dielectric strength is the illustrated insensitivity of the arc resistance rise (and dielectric recovery) to restored voltages less than 70 per cent of the critical values coupled with the fact that circuit interrupters normally operate with factors of safety such that α is much less than 70 per cent. Thus, contrary to Skeats' observation, the curves for $\alpha = 0$ are actually of more practical significance than those for the critical restored voltage ($\alpha = 1$).

With most of the other points in the discussion by Skeats, I find myself in general agreement. He is certainly correct in pointing out that the usefulness of the presented simple model is limited by the assumption of no mutual interaction between arc voltage and current. Figures 8*b* and 8*c* for the square law rise do glaringly show this defect, but this idealized voltage recovery case was included because of its possible interest in comparison with the linear rise case of Figure 7 for times somewhat after current zero. The "transition" region very near current zero needs to be treated by some such method as that used by Cassie.

Cassie's discussion is especially appreciated because of my dependence on his earlier work. I am grateful for the further light on his admittedly obscure Paris conference presentation and hope that he will see fit to publish a still more nearly complete account of his calculations in the near future. The segregation of the extinction period into four periods by Cassie does help to clarify the over-all picture, but, as he remarks, practical difficulties arise in considering the transition between these periods which may make necessary combined treatment of some of them. I quite agree with Cassie in his criticism of Mayr's paper (Reference 5 of my paper).

In conclusion, I wish belatedly to call attention to some additional residual arc current records, similar to Lewis' and ours but in a higher power circuit, published in Stockholm in 1946 by Doctor P. Hammarlund.[4]

A Compressed Air Circuit Breaker for 23-Kv Arc Furnace Duty

H. M. WILCOX
MEMBER AIEE

B. P. BAKER
MEMBER AIEE

THE FIRST SWITCHES for the control of electric circuits combined the functions of switching, protecting and controlling the circuit, in any manner applied. As the range of operating voltage and current expanded, these functions gradually became segregated, the main power circuit breaker assuming the duty of switching and fault protection on high powered circuits while lighter interrupting devices were employed for control of industrial equipment. With the advent of the electric arc furnace, localized intermittent power requirements extended the operating voltage and current range to a point which taxed the ability of industrial control devices and the need of heavier control equipment became evident.

To meet this situation, available oil circuit breakers were drafted into furnace service and applied generally on the high side of the furnace transformers. In addition to their duty controlling the flow of current to the furnace, these circuit breakers were relayed to provide full fault protection for the high voltage furnace feeders. Thus, the circuit breaker had at all times to be in condition to interrupt its full short circuit current rating on a primary fault, ranging up to thousands of amperes, while performing the repetitive duty of a contactor where perhaps 90 per cent of its operations involve the interruption of transformer magnetizing current, generally less than 30 amperes, together with some load current switching involving a few hundred amperes.

Unfortunately, the then available oil circuit breaker possessed an arcing time–current interrupted characteristic which rendered it somewhat unsuited to this application. Its maximum arcing time[1,2] generally coincided with the low range of current at which most of its interrupting operations occurred. The long arcing time on these low current interruptions on a highly inductive circuit resulted in undue amounts of arc energy accompanied by repeated high voltage surges. Since this class of interruption occurred anywhere from 30 to 100 times a day, this resulted in rapid deterioration of oil, and increased maintenance.

As a move toward improving this situation, the air insulated De-ion circuit breaker[3] was introduced into steel mill service in 1932, the first arc furnace application at 13,200 volts being made in 1937. By comparison with previous experience, the performance of these circuit breakers was most gratifying; the oil fire hazard was eliminated, intervals between maintenance periods were doubled and trebled, replacement of operating parts was very materially reduced and interruptions to furnace operation reached a minimum.

A further improvement was obtained by the use of a small cylinder and piston attached to the operating mechanism of the circuit breaker, so arranged as to produce a light blast of air past the parting contacts to assist the magnetic field in forcing the arc into the interrupting chamber. Capacitors, connected from the high voltage leads of the furnace transformer to ground have been used with some success in reducing high voltage surges, although their use appears most effective in reducing surges having their origin in the furnace rather than those associated with switching.[4,5]

Analysis of operating experience up to this time led to the present recommended practice divorcing the primary fault protection function of furnace circuit breakers from the highly repetitive, low current switching operations.[6] This provides a single back-up circuit breaker for protection of the feeders to a battery of furnace transformers, each transformer to have an interrupter specially designed for highly repetitive, low current duty to act as a furnace control but to remain closed under primary fault conditions.

Under this arrangement, the De-ion circuit breaker, being somewhat of a constant current device whose arcing chamber, and consequently the complete circuit breaker structure, depends for size more largely on the voltage to be interrupted rather than the current, was not well adapted to this application. A further trend toward the use of higher voltages in the primary circuit made the use of this circuit breaker still more limited in application, and the field of interrupting devices was canvassed for a more suitable circuit breaker.

The achieved success of the compressed air circuit breaker for power house service[6,7] and its constant arcing time characteristics on low currents, has prompted its development for arc furnace service where reliability, continuity of service and safety are required. These requirements were met by building the circuit breaker, as shown in Figure 1, on a rugged supporting frame with all moving parts mounted on and connected through sealed ball bearings. The contacts and arc splitters, which are the only expendable materials, are accessible for inspection to a man standing on the ground when the circuit breaker is in the open circuit position. These parts are also easily and quickly replaced. All insulating parts are liberally dimensioned for electric integrity and made from various grades of "Micarta" insulation to give a strong, rigid shockproof structure. Surge suppressors, Figure 2, are supplied for use with the circuit breaker, which are introduced in the circuit in parallel with the arc dur-

Paper 48-24, recommended by the AIEE switchgear committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted November 12, 1947; made available for printing December 4, 1947.

Figure 1. A 600-ampere 23,000-volt compressed air circuit breaker for highly repetitive electric arc furnace service

Figure 2. Surge suppressor for use with electric arc furnace circuit breaker

ing the opening and closing operations of the circuit breaker. Their use has reduced the overvoltages to less than one-half of their normal value over the most active current range from 10 to 100 amperes.

The *230-CAF* compressed air circuit breaker shown in Figure 1, has a continuous current rating of 600 amperes with an interrupting rating of 3,000 amperes, and is provided with 34.5-kv class insulation for 23-kv service. It is of the open-frame mounting type and may be located safely in the transformer vault or similar room. As shown in Figures 1 and 3, the circuit breaker frame houses the air storage reservoirs, the pneumatic mechanism, blast valves, control panel and all other parts operating at ground potential. The mechanism consists of a single cylinder and piston, operated by air for both closing and opening. The connecting rod operates the main shaft through two sets of links which form a toggle lock when the circuit breaker is in the closed circuit position. This shaft in turn operates the three moving contacts and the three blast valves. The contacts are connected to the main shaft by wood "Micarta" insulating rods. The blast valves are connected to the main shaft by a simple system of links, which forces the valve open against air pressure during the opening stroke of the circuit breaker, but permits the valves to remain closed during the closing stroke of the circuit breaker. All contacts and blast valves are therefore mechanically tied together and operated in unison by a single pneumatic mechanism. Their adjustment is such that the blast valves open slightly before the contacts separate, but then reclose soon after the contact is withdrawn from the interrupter. To prevent mechanical shock during operation, the moving system is decelerated at both ends of its travel by automobile shock absorbers which are also attached to the main shaft.

All live parts including the contacts, their operating rods, the air blast tube shown in Figure 4, and the interrupter shown in Figure 5 are mounted on top of the frame in open view, although a grill enclosure may be mounted around the circuit breaker when further protection to personnel is desired. The contacts are of the bayonet and finger type. The moving contacts, or bayonet, is hinged at the lower end and rotated back and forth to the open and closed position. Figure 4 shows the moving contact in the almost closed position. When in the open position as shown in Figure 1, the moving contacts are completely withdrawn from the interrupters, so that voltage is removed from the interrupters, leaving the stationary contact and fiber splitters in full view. The interrupter is mounted at the end of the "Micarta" blast tube, adjacent to the stationary contacts, so that the arc is drawn perpendicular to the ends of the splitters which are disposed over the end of the air blast tube. The arc is thus extinguished by the blast of air forcing it against the ends of the fiber splitters.[6] This interrupter is quite different from those used on power house circuit breakers where large values of

Figure 3. Sectional elevation showing the circuit breaker in Figure 1

Figure 4. Contact and blast tube assembly, showing the contacts in the almost closed position

Picture taken after 110,000 operations, 30,500 with power

current have to be interrupted. On the power house circuit breakers four of five diverging splitters with intermediate coolers are used. On the furnace circuit breaker eleven simple fiber splitter plates are used. These are mounted parallel and spaced apart without coolers as shown in Figure 5. At the front end of the interrupter is a metal probe extending into almost engaging relation with the moving contact. The surge suppressor is connected to this probe and to the stationary contact. When the circuit breaker is opened, the arc is drawn in the interrupter, and the surge suppressor is connected in parallel with the arc through a very short air gap between the probe and moving contact. The rate of rise of the recovery voltage is thus controlled and the magnitude of the overvoltages limited by the conductivity of the surge suppressor. After the main arc has been extinguished and the moving contact withdrawn from the interrupter, the residual current in the surge suppressor is extinguished between the probe and the moving contact.

The surge suppressor, as shown in Figure 2, consists of a group of lightning-arrester disks, hermetically sealed in a procelain container and mounted on an insulating pedestal. The lightning-arrester disks have a nonlinear resistance characteristic, which permits them to carry large values of current when the applied voltage attempts to go beyond a predetermined value, but for normal crest line voltage the current is limited to a value which is easily interrupted as the moving contact is withdrawn from the interrupter. This characteristic also decreases the amount of energy which would have to be dissipated in the suppressor. The surge suppressor as a complete assembly may be mounted on the circuit breaker or placed at any convenient location.

Figure 5. Schem tic diagram of arc chute

Figure 6. Schematic diagram of the testing circuit

Operating Pressure

The circuit breaker is designed to operate at a pressure of 100 pounds per square inch, but has been demonstrated down to 60 pounds per square inch. This permits the use of the shop air supply, which however, is recommended for emergencies only. Normally, a separate air supply should be provided, which may be adequate for several circuit breakers, depending upon the service requirements. The air supply unit consists essentially of an electric motor, a 2-stage air compressor, and storage reservoirs, in which air is stored at 250 pounds per square inch, there it is cooled, and expanded to the circuit breaker operating pressure of 100 pounds per square inch which leaves it clean and dry.

Test Circuit

Figure 6 is a schematic diagram of the test circuit which was set up in the laboratory to check the operation of the circuit breaker under conditions approximating those found in service. One and some times two 20,000-kva 3-phase 13.2 kv Y-connected grounded neutral generators were used as the source of power. Following the generator circuit breaker was a 3-phase bank of air-core reactors to control the current. From there power was supplied to the high side of a bank of 3-phase 100,000-kva transformers connected 13.2 kv to 38 kv. The low side of the transformer bank was connected in delta, and the high side wye with a grounded neutral for most of the tests. This gave a rather stiff source of variable power similar to that which may be found in

service. On the load side of the test circuit breaker was another 3-phase 100,000-kva bank of transformers, connected 230 kv to 13.2 kv. The high side which was next to the test circuit breaker was wye-connected and ungrounded for most of the tests. The low side was in delta. One-fourth-microfarad capacitors were provided for grounding the load terminals of the circuit breaker on some of the tests. The load beyond the transformer consisted of another bank of 3-phase air-core reactors. In some respects, this type of load is quite different from an arc furnace. However, the switching surges are found to be just as severe. Current and potential transformers for use on recording devices were located as shown. Cathode ray oscillograph connections were made as shown to obtain a record of the voltage surges from line to ground, load to ground and across the circuit breaker. By varying X_{L1}, X_{L3}, the transformer ratio on both banks and the generator excitation, a wide range of current and voltages could be obtained.

Test Results

The circuit breaker was given over 110,000 operations, 30,500 of which were with power. Generally the power tests were interspersed with groups of tests without power. Most of the tests were on a 3-phase basis with 23 kv line-to-line. Current values from 0.3 to 200 amperes were obtained by keeping X_{L1} constant at 5 ohms and varying X_{L3} from infinity to zero. With X_{L1} constant at 0 ohms and X_{L3} varying from infinity to 0.073 ohm, currents up to 1,200 amperes were obtained with one generator as shown in Figure 6. With two generators 1,600 amperes were obtained. By increasing the excitation of the generators to give $34^1/_2$ kv at the circuit breaker terminals currents up to 2,250 amperes were obtained. For currents around 3,000 amperes, the circuit-breaker terminals were short-circuited before going into the transformer, and the generator excitation adjusted to give a test voltage of 27.6 kv. For 3,500 amperes, the excitation was raised to 36 kv.

The tests performed were distributed over the current range generally as they may appear in service. About 500 operations were between 1,400 and 3,500 amperes; 3,000 between 300 and 500 amperes, and the remainder around 20 amperes where the overvoltages seem to be the greatest. Figure 7A is a curve showing the surge voltage across the test circuit breaker plotted as a function of current interrupted for a circuit as shown in Figure 6. The dots represent the tests without any voltage-suppressing means. The circles represent the tests in which the surge suppressor was used. The numbers to the right of the points indicate the number of times during that test that the voltage reached 75 per cent or more of the voltage indicated by the point; namely, at 30 amperes, 23 kv, without the surge suppressor, the voltage reached a maximum of 105 kv and three additional times it came to 79 kv or more. This represents 5.6 times normal line-to-ground voltage which is in good agreement with published steel mill data.[8] Figure 7B is a similar curve made under the same circuit conditions as Figure 7A, except the load terminals of the circuit breaker were connected to ground through a 1/4-microfarad capacitor. From these curves, it appears that the surge suppressor may be relied upon to reduce the overvoltages to approximately 40 per cent of their free value.

Since this type of interrupter develops interrupting ability as the arc is drawn across additional splitters, the arcing time or arc length is an indication of interrupting effort. It has been observed that the arcing time bears a direct relation to the magnitude of the voltage surges. The arcing time has a maximum between 10 and 100 amperes for the free oscillating circuit. When the surge suppressor is used, the arcing time is quite uniform and seldom exceeds one cycle.

The use of the grounding capacitor on the load lead has very little effect on the overvoltages across the circuit breaker except to slightly shift the range of current where maximum overvoltage occurs to higher current values. If the use of the ca-

C. Circuit with $^1/_4$-microfarad grounding capacitor without surge suppressor
D. Circuit with $^1/_4$-microfarad grounding capacitor with surge suppressor

pacitor moves this maximum overvoltage range away from the most active current range, an apparent operating improvement would be observed. Removing the ground from the power bank of transformers and grounding the load bank showed no noticeable difference in the voltage surges across the test circuit breaker.

Several tests made with the cathode ray oscillograph connected from the line terminal to ground and from the load terminal to ground, indicated that the overvoltages to ground were about equal in both cases, and were only about one-half of the voltage across the circuit breaker as shown in Figures 7A and 7B.

Figure 8 shows the magnetic and cathode-ray oscillogram of four representative tests. It should be noted that the cathode-ray oscilloscope voltage scales are not the same for all four tests.

1. Normal circuit without surge suppressor.
2. Normal circuit with surge suppressor.
3. With grounding capacitor and without surge suppressor.
4. With grounding capacitor with surge suppressor.

All four tests were made on the circuit shown in Figure 6, 24.7 kv at 15 amperes.

Conclusion

A compressed-air circuit breaker has been developed for highly repetitive duty in electric arc furnace service. An intensive series of tests has demonstrated that with its strong, shock-resistant construction and with all parts designed for repetitive duty, this circuit breaker is capable of withstanding many thousands of operations in the current ranges of magnetizing, load and secondary fault currents, when operated at normal shop air pressure. A life test of 30,000 interruptions in these current ranges has been made on this circuit breaker without repairs, replacement of contacts or any other operating element.

The use of a nonlinear resistance surge suppressor across the circuit-breaker terminals during arcing, is recommended to reduce surge voltages to less than 40 per cent of their normal free value which may reach six times line-to-ground voltage in the current range from 10 to 100 amperes.

J. S. WILLIAMS
ASSOCIATE AIEE

EVALUATION OF TORQUES which develop in turbine generators during circuit reclosing or synchronizing operations deserves detailed analysis, even though in existing installations and under normally contemplated conditions it is unlikely that many machines will be mechanically stressed beyond recommended limits. The integrated procedure described here is primarily intended to supply a quantitive check on those future installations which, because of generally lower machine and system impedances, may prove more critical than those now in service. High-speed reclosing tie lines are the most frequently encountered system components which allow circuit reclosing while phase displacement exists, but other components or situations may be responsible for three pole synchronizing out of phase, and will also be subject to the analysis given here.

In addition to the detailed methods applicable to the final analysis of a critical case, a basis for estimating the severity of transient torques should prove valuable for identifying those situations which will require complete solution.

System losses and decrements are important in their effect on the magnitude of peak transient torques, and no solution of a critical case should be considered complete without modifications based on system resistances and decrements within the machine.

Electrical Torque In No Loss Circuits

To evaluate the total mechanical torque developed in a turbine generator shaft during 3-phase synchronizing, it is first necessary to solve the electrical system for the torque developed between rotor and stator of the generator. This torque is basically dependent upon the interaction of currents and magnetic fields within the machine,[1] but may be more conveniently expressed in terms of the machine internal voltage, machine impedance, system impedance, and angular displacement between system and machine voltage at the instant of reclosure.[2] Figure 1*a* is an equivalent circuit, showing one phase of a circuit which contains the essential quantities to be dealt with in a no-loss no-decrement circuit. Development of an equation which represents the variation of electrical torque immediately following circuit closure, as is outlined in Appendix II, indicates that two components combine to form resultant transient electrical torque. One is a constant torque produced by rotating field flux and alternating armature current, and the other is an alternating fundamental frequency torque produced by rotating field flux and the direct component of initial armature current. These two torque components combine in proportions which are determined by the angle of reclosure. A unique feature of the problem is the angle at which these two torque components combine to form a unidirectional torque peak. If the machine voltage is advanced with reference to system voltage prior to reclosing, a maximum torque impulse tending to retard the machine will occur when the reclosing angle is 120 degrees. Figure 2 is a sketch of the transient electrical torque throughout two cycles, based on reclosing angles of 120 and 240 degrees. The peak unidirectional torque will vary in magnitude along with a change in the reclosing angle, as indicated in Figure 3. It is important to note that circuit reclosure must occur simultaneously on the three phases if this analysis is to be valid.[3]

Electrical Torques in a Circuit Which Contains Loss and Decrement

Sources of power loss and current decrement that will always exist in an actual circuit, and almost always affect electrical torque to a degree worthy of consideration, are listed here:

1. Armature resistance of generator.
2. Circuit resistance external to generator.
3. Decrement of direct components of current in armature circuit.
4. Decrement of subtransient components of current in armature.
5. Decrement of internal voltage of machine.
6. Losses within the machine which produce "loss torques."

In the derivation outlined in Appendix III, the foregoing modifying factors have been applied to the basic equation of the previous section in a manner which must admit to some approximation, but which is believed to be comparable in accuracy with other working methods widely used in synchronous machine analysis.

One outstanding factor remains, however, to limit the applicability of the results shown here to the first one or two cycles immediately following circuit re-

Paper 48-25, recommended by the AIEE rotating machinery, system engineering, and transmission and distribution committees and approved by the technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted November 12, 1947; made available for printing December 23, 1947.

closure. It is the reduction in angular displacement between machine and system which will proceed following circuit reclosure. So long as maximum torques are to be derived, conditions which develop after the first two cycles are of secondary importance.

Solution of Electrical Torques by Network Calculator

Seldom will a synchronizing problem involve electrical circuits that can be readily reduced to an equivalent single mesh network. To provide for the probability that complex networks will appear in connection with torque problems, and to combine torque and system stability problems whenever the system involves a high-speed reclosing tie, a calculating method applicable to the a-c network calculator has been devised.

If a power system is set up for study on an a-c network calculator, the change in machine armature currents produced by any circuit reclosing operation may be measured for various combinations of system loading and interconnection. Since subtransient currents determine peak torque values, the transient values of machine impedance normally used during stability studies should be replaced by subtransient values, but only at the instants of time which immediately precede and follow the reclosing operation. To obtain a guide to the application of loss and decrement factors, the equivalent system impedance external to the generator after reclosure should be measured with system voltages removed. With these quantities determined, a solution for transient electrical torque may be established according to the derivation in Appendix IV. Load torque which exists on a machine just prior to a reclosing operation tends to retard the generator, and should be added in proper sense to transient mechanical torque in order to obtain total shaft torque.

Application of the Electrical Analog Computer to the Determination of Transient Shaft Torques Produced by Synchronizing Out of Phase

The use of the electrical analog computer in the solution of linear differential equations is well known.[6] Essentially the solution consists of the determination of an electrical network whose differential equations for voltage and current are analogous to the equations to be solved. Boundary conditions are imposed on the input function to the network analogy as dictated by the original differential equations that are to be solved. The solutions are obtained in the form of direct readings or pictures from an oscilloscope which is connected by means of metering buses to points in the analogy, thereby permitting a direct reading of any of the desired unknowns.

The problem to be solved in the case of synchronizing out of phase is the determination of the maximum torque which will be developed in the shaft of a turbine-generator unit which is synchronized out of phase over the range of 0 to 180 degrees.

The torque developed in the rotor during synchronizing takes the form

$$T=Ae^{-\lambda t}-Be^{-\alpha t}\cos\omega t+Ce^{-\gamma t}\sin\omega t \quad (1)$$

where A, B, and C are functions of δ where δ is the angle of synchronizing; λ, α, and γ are decrement factors. This torque acts on the mechanical system consisting of the generator rotor, with an inertia constant I_1, the generator to turbine shaft having a spring constant K, and the turbine with an inertia constant I_2.

The equation for dynamic equilibrium of the mechanical system is given by

$$T=I_1\frac{d^2\theta_1}{dt^2}+K(\theta_1-\theta_2) \quad (2)$$

and

$$O=I_2\frac{d^2\theta_2}{dt^2}+K(\theta_2-\theta_1) \quad (3)$$

where

T = input torque to the generator rotor
I_1 = inertia constant of the generator rotor
I_2 = inertia constant of the turbine rotor
θ_1 = angular displacement of the generator rotor relative to synchronous position
θ_2 = angular displacement of the turbine rotor relative to synchronous position
K = spring constant of shaft connecting the generator and turbine

If a mass-inductance analogy is used, voltage will correspond to torque, current to velocity, and charge to displacement. A simple circuit which will produce voltage components corresponding to the terms of the torque equation 1 is shown in Figure 4.

The electrical analogy for the mechanical system is shown in Figure 5. The correspondence between the electrical network of Figure 5 and the mechanical system can be readily seen by writing the equations for dynamic equilibrium in

Figure 2. Variation of per unit electrical torque following circuit reclosing

Reclosing angles are (a) 120 degrees and (b) 240 degrees, with $E_a^2/(X_d''+X_s)$ equal to 10

Figure 3. Magnitude of crest per unit electrical torque

Developed by reclosing angles between 0 and 360 degrees, with $E_a^2/(X_d''+X_s)$ equal to 10

terms of voltage and charge for the network.

$$e = L_1\frac{d^2q_1}{dt^2} + \frac{1}{c}(q_1 - q_2) \tag{4}$$

$$O = L_2\frac{d^2q_2}{dt^2} + \frac{1}{c}(q_2 - q_1) \tag{5}$$

Note the similarity between equations 2 and 4, and 3 and 5. The second term in equations 4 and 5 represents the voltage drop across the capacitor, and since voltage is analogous to torque, gives directly the torque developed in the shaft.

For general studies it is advantageous to reduce the 2-mesh circuit of Figure 5 to an equivalent single-mesh circuit. Rewriting equations 4 and 5 in terms of the currents i_1 and i_2 and the differential operator, p, we have

$$e = L_1 p i_1 + \frac{1}{cp}(i_1 - i_2) \tag{6}$$

$$O = L_2 p i_2 + \frac{1}{cp}(i_2 - i_1) \tag{7}$$

Multiplying equation 7 by $\frac{L_1}{L_2}$ we have

$$O = L_1 p i_2 - \frac{L_1}{L_2}\,\frac{(i_1 - i_2)}{cp} \tag{8}$$

Thus

$$e = L_1 p(i_1 - i_2) + \left(\frac{L_1 + L_2}{L_2}\right)\left(\frac{i_1 - i_2}{cp}\right)$$

Equation 9 suggests a single-mesh circuit as shown in Figure 3, where $L_0 = L_1$

$$C_0 = C\left(\frac{L_1 + L_2}{L_2}\right) \tag{10}$$

Figure 5. Electrical analogy for turbine generator

$$i_0 = i_1 - i_2 \tag{11}$$

and e_{c0} is analogous to T_o and e_c is analogous to T, giving a ratio between T and T_o of

$$\frac{T}{T_o} = \frac{L_2}{L_1 + L_2} \tag{12}$$

The natural frequency of the system is given by

$$f = \frac{1}{2\pi}\sqrt{\frac{L_1 + L_2}{L_1 L_2 C}} \text{ cycles per second} \tag{13}$$

This permits us to reduce the shaft torque as a function of frequency to a general curve independent of the turbine inertia. In Figure 7 are curves showing the crest transient torques developed in the shaft for various angles of synchronization as determined on the electrical analog computer.

Figure 4. Forcing function for air gap torque analogy

Maximum Mechanical Torque Considerations

American standards require that a generator "shall be capable of withstanding, without injury, the stresses of a 10-second, 3-phase short circuit at its terminals when operating at rated kilovolt-amperes, power factor, and 5 per cent overvoltage, or any other 10-second short circuit provided the machine phase currents under the fault condition are limited by means of suitable reactance or resistance to a value which does not exceed the maximum phase current obtained from the 3-phase fault."[7] This requirement serves to define the capability of the shaft with respect to the peak torque which may be applied, and may be used as the criterion for the maximum torque to be developed in the case of out-of-phase synchronizing, since no specific standard has been defined for that particular case. It has been shown[8] that the most severe shaft torque for normal design turbine generators with a mechanical system frequency of the order of 30 cycles per second is developed in the case of a line-to-line fault at the generator terminals with the machine operating at 105 per cent voltage and full load. The torque under this condition, then, is that for which the shaft is designed, and that which should not be exceeded under any other operating condition. A fault at the terminals of the generator is relatively improbable, and the out-of-phase synchronizing condition is one which may occur relatively frequently on systems where 3-phase reclosing is used. Therefore, the maximum allowable torque which should be developed under the latter condition should be somewhat less than the maximum allowable torque for which the machine was designed, in order that the unit may not be repeatedly subjected to the most severe shocks allowable. A figure of 75 per cent of the torque obtained on a line-to-line fault at the full load and 105 per cent voltage has been used in this study for the maximum allowable torque for the out-of-phase synchronizing condition.

Figure 6. Equivalent single-mesh circuit for turbine generator analogy

Figure 8 shows the relation of shaft torque and synchronizing angle for a typical 30,000-kw 85-per cent power factor, 3600-rpm 60-cycle turbine generator with a 2-mass mechanical system. For this same unit, the shaft torque for a line-to-line fault at full load and 105 per cent voltage is 4.35 times normal. Thus, for the condition just referred to, the maximum allowable torque would be 3.25 times normal, and the maximum allowable synchronizing angle may be determined from Figure 8 for various values of system reactance.

While the shaft torque reaches a maximum for a synchronizing angle of approximately 120 degrees, the forces on the stator winding reach a maximum at a synchronizing angle of 180 degrees. As in the case of the maximum allowable shaft torque, the forces on the stator winding resulting from the relatively frequent out-of-phase synchronizing should be limited to some value less than that for which the machine was designed, and for this limit a value of 75 per cent of the forces caused by a 3-phase fault at the generator terminals with the machine operating at full load and 105 per cent voltage has been

Figure 7. Crest shaft torque for typical 30,000-kw turbine generator

$X_s = X_d = 0.109$ per unit
$E_a = E_s = 1.03$ per unit

used. Figure 9 shows the allowable limits of system reactance and synchronizing angle for maximum forces on the shaft and stator windings for the 30,000-kw generator referred to previously. Conditions which lie within the cross-hatched area are unsafe.

Probability of Developing Excessive Torques by Transmission Line Reclosing

Most applications of high-speed tie line reclosing inherently involve factors which will limit the repetitive torques to values below recommended limits. Relatively high decrements associated with transmission circuits and the presence of other transmission lines effectively paralleling the reclosing tie line will act to reduce electrical torques.

If a paralleling tie line should be out of service at a time when the reclosing sequence proceeds, stresses greater than normally anticipated will occur in connected machines. Lightning storms may affect an area so that line outage and reclosing will occur coincidentally on adjacent transmission lines.

Several methods have been considered to reduce the possibility of such undesirable results of simultaneous faults, and among the most practicable is single pole tie line reclosing. This plan arranges for only the faulted phase of a transmission line to be opened and reclosed automatically, leaving unfaulted phases available to keep the system stable and prevent the development of a large reclosing angle. If a fault involving more than one phase develops, automatic reclosing may be prevented by lock-out devices.

Appendix I. Nomenclature

X_d'' = subtransient reactance of machine
X_d' = transient reactance of machine
X_2 = negative sequence reactance of machine
X_s = reactance of system external to machine
R_a = d-c resistance of machine armature circuit
R_s = resistance of circuit external to machine
R_1 = positive sequence resistance of machine
R_2 = negative sequence resistance of machine
E_a = phase to neutral vector voltage behind machine subtransient reactance, in per unit based on rated machine voltage
E_s = phase to neutral vector voltage of reference phase system voltage, expressed in per unit based on rated machine voltage
e_a = instantaneous value of E_a (maximum $e_a = \sqrt{2}\,|E_a|$)
e_s = instantaneous value of E_s (maximum $e_s = \sqrt{2}\,|E_s|$)
I_a = current in machine armature circuit, expressed in per unit based on machine rated current
i_a = instantaneous value of I_a (maximum $i_a = \sqrt{2}\,|I_a|$)
T_d'' = time constant of subtransient component of a-c armature current
F = decrement factor applicable to short circuit alternating currents in machine armature
F' = decrement factor applicable to synchronizing alternating currents in machine armature
F'' = decrement factor applicable to synchronizing alternating currents in machine armature, similar to F' except derived from a-c network calculator information
A = decrement factor applicable to direct currents in machine armature
δ = angle by which machine internal voltage leads system voltage at moment of synchronizing
T = electrical torque developed between rotor and stator of generator, in per unit based on machine output at rated voltage, rated current, and unity power factor. The torque is expressed as a positive quantity when it acts in a direction to retard the machine's rotation
T_L = loss torque produced in machine during reclosing
θ = power factor angle of complete circuit, including machine and system impedances
ϕ = reactive factor angle of complete circuit ($\phi = 90 - \theta$)
β = angle between internal machine voltage and armature current (The angle is negative when current lags the internal machine voltage)

Note: All impedances are expressed in per unit on the machine kilovolt-ampere base.

Figure 8. Crest shaft torque of 30,000-kw turbine generator as a function of synchronizing angle and system reactance

Three phase synchronizing. Mechanical frequency 23.3 cycles per second
$I_1 = 8{,}800$ lb in. sec^2, $I_2 = 10{,}500$ lb in. sec^2

Appendix II. Three-Phase Electrical Synchronizing Torque in Basic Circuit

Making the two assumptions that losses and decrements are negligible and that the machine and system voltages are equal in magnitude, the following derivation is based upon Figures 1*a* and 10, and provides an expression for electrical torque in the synchronized machine.[3]

$$\delta = 2\alpha \tag{14}$$

$$E_a = |E_a|\,\epsilon^{j\alpha} \tag{15}$$

$$E_s = |E_a|\,\epsilon^{-j\alpha} \tag{16}$$

Figure 9. System reactance required with 30,000-kw turbine generator for safe synchronizing, as a function of synchronizing angle

Three-phase synchronizing

$$E_a - E_s = j2|E_a| \sin \alpha \tag{17}$$

$$I_a = \frac{E_a - E_s}{j(X_d'' + X_s)} = \frac{2|E_a| \sin \alpha}{X_d'' + X_s} \tag{18}$$

Real components of the machine internal voltages follow from equation 15.

$$e_a = \sqrt{2}|E_a| \cos (\omega t + \alpha) \tag{19}$$

$$e_b = \sqrt{2}|E_a| \cos (\omega t + \alpha + 240) \tag{20}$$

$$e_c = \sqrt{2}|E_a| \cos (\omega t + \alpha + 120) \tag{21}$$

Real components of machine armature currents, including d-c terms, follow from equation 18.

$$i_a = \frac{2\sqrt{2}|E_a| \sin \alpha}{X_d'' + X_s} [\cos \omega t - \cos 0] \tag{22}$$

$$i_b = \frac{2\sqrt{2}|E_a| \sin \alpha}{X_d'' + X_s} [\cos (\omega t + 240) - \cos 240] \tag{23}$$

$$i_c = \frac{2\sqrt{2}|E_a| \sin \alpha}{X_d'' + X_s} [\cos(\omega t + 120) - \cos 120] \tag{24}$$

$$T = {}^1/_3(e_a i_a + e_b i_b + e_c i_c) \tag{25}$$

$$= \frac{|E_a|^2 \sin \delta}{X_d'' + X_s}\left[1 - \cos \omega t + \tan \frac{\delta}{2} \sin \omega t\right] \tag{26}$$

$$= \frac{|E_a|^2}{X_d'' + X_s}\left[\sin \delta - 2 \sin \frac{\delta}{2} \cos \left(\omega t + \frac{\delta}{2}\right)\right] \tag{27}$$

Appendix III. Derivation of Transient Electric Torque Considering Losses and Decrements

This section is based on the circuit of Figure 11, the plan being first to determine electrical torque caused by that portion of system voltage which is equal in magnitude to machine voltage, and then to superpose the effect of the remaining component of system voltage.

$$T = T' + T'' + T_L \tag{28}$$

$$Z = R_1 + R_s + j(X_d'' + X_s) \tag{29}$$

$$\theta = \tan^{-1}\left(\frac{X_d'' + X_s}{R_1 + R_s}\right) \tag{30}$$

$$\phi = 90 - \theta \tag{31}$$

Figure 10. Vector diagram associated with the basic equivalent circuit shown in Figure 1a

Applying a field decrement factor to the real component of machine internal voltage:

$$e_a = \sqrt{2}|E_a| F' \cos (\omega t + \alpha) \tag{32}$$

Introducing direct current components and applying appropriate decrement factors:

$$i_a' = \frac{2\sqrt{2}|E_a| \sin \alpha}{Z} [F' \cos (\omega t + \phi) - A \cos \phi] \tag{33}$$

$$T' = \frac{2|E_a|^2}{Z} \sin \frac{\delta}{2} \cos \left(\frac{\delta}{2} + \phi\right)\left[F'^2 - F'A \cos \omega t + F'A \tan \left(\frac{\delta}{2} + \phi\right) \sin \omega t\right] \tag{34}$$

Figure 11. Circuit and diagram of circuit which contains resistance and voltages of unequal magnitude

The torque component which must be combined with T' in the event that internal machine voltage does not equal system voltage is derived below, assuming that E_s exceeds E_s'.

$$E_d = E_s - E_s' = |E_d| e^{-j\alpha} \tag{35}$$

$$T'' = \frac{|E_d||E_a|}{Z_1} \sin (\delta - \phi)[F''^2 - F''A \cos \omega t + F''A \cot (\delta - \phi) \sin \omega t] \tag{36}$$

If E_s' should exceed E_s, the sign of T'' will be reversed.

Loss torques in the machine act always to retard the rotor, hence their algebraic sign will be positive according to the assumptions of this paper. To approximate the loss torque, the condition of synchronizing two identical machines at a 180 degree closing angle is considered. This is equivalent to the 3-phase fault condition, for which loss torques are known. Since the loss torques are dependent upon internal machine voltage, a factor of reduction for this voltage which is a function of the reclosing angle seems to be appropriate.

$$T_L = \sqrt{2}\left[\frac{\sqrt{2}A}{(X_d'' + X_s)}|E_a| \sin \frac{\delta}{2}\right]^{1.8} (R_2 - R_1) + \left[\frac{2F'}{X_d'' + X_s}|Ea| \sin \frac{\delta}{2}\right]^2 \left(R_1 + \frac{R_s}{2}\right) \tag{37}$$

Figure 12. Circuit representative of reclosing operations which occur within a complex system network

Appendix IV. Derivation of Transient Electrical Torque From Information Furnished by A-C Network Calculator

The following quantities, identified in Figure 12, should be measured at the machine:

E_a = Voltage behind subtransient reactance, determined during a stability study by replacing all machine transient reactances with subtransient reactances, and readjusting internal voltages to maintain identical system conditions. These changes are to be made at the instant immediately before a circuit reclosing operation occurs within the network

ΔI_a = Change in machine current caused by a switching operation within the network, measured in complex form relative to E_a

Z_s = Impedance of network after circuit reclosure has been accomplished, measured with all network voltages zero

$$e_a = \sqrt{2}F'' |E_a| \cos \omega t \tag{38}$$

$$\Delta i_a = \sqrt{2} |\Delta I_a| [F'' \cos (\omega t + \beta) - A \cos \beta] \tag{39}$$

$$T = |E_a| |\Delta I_a| [F''^2 \cos \beta - F''A \times \cos (\omega t - \beta)] \tag{40}$$

To approximate decrement factors and loss torques, β and $\delta/2$ may be considered of equal magnitude.

Appendix V. Decrement Factors

Decrement of direct current components in the armature is the more important of the two decrements considered here:

$$A = \epsilon^{-t[2\pi f(R_a + R_s)(X_a + X_s)]} \tag{41}$$

Decrement of the subtransient quantities (a-c armature current and voltage behind subtransient reactance) within the machine is complicated by several factors not present in short circuit problems. First, the system contains a machine internal voltage which will decay, and a system voltage which has been considered constant. Second, the current which circulates within the armature is not always completely effective in demagnetizing the main field of the machine because of its large quadrature axis component at small reclosing angles. One approach to a solution is to assume that the machine is synchronized with a system

whose characteristics are in all respects identical to the machine's. At a synchronizing angle of 180 degrees, then, the currents and voltages in the machine will appear as if a 3-phase short circuit had been applied to the machine terminals, and previously developed subtransient decrement factors will apply.[2,3,5]

$$F = \frac{X_d''}{X_d'} + \frac{X_d''(X_d' - X_d'')}{X_d''X_d'}\,\epsilon^{-\frac{t}{\tau_d''}} \qquad (42)$$

The demagnetizing effect of armature current will be produced by current in the direct-axis of the machine. The direct-axis component of armature current varies as $\sin \delta/2$, so a modified field decrement is:

$$F' = \frac{X_d''}{X_d'} + \frac{X_d''(X_d' - X_d'')}{X_d''X_d'} \times \left[1 - \left(1 - \epsilon^{-\frac{t}{\tau_d''}}\right) \sin \frac{\delta}{2}\right] \qquad (43)$$

When the actual system characteristics depart markedly from those of the machine, a factor replacing $\sin(\delta/2)$ can be determined by calculating the actual ratio of direct axis armature current to total armature current.

In calculating T'', a different form of equation 43 should be used:

$$F'' = \frac{X_d''}{X_d'} + \frac{X_d''(X_d' - X_d'')}{X_d''X_d'} \times \left[1 + \left(1 - \epsilon^{-\frac{t}{\tau_d''}}\right) \sin \beta\right] \qquad (44)$$

Discussion

A. W. Rankin (General Electric Company, Schenectady, N. Y.): The subject paper has presented an analysis of the shaft torques in turbine-generators during reclosing operations, and has made several statements concerning the "allowable limits of system reactance" during such reclosing operations.

In discussing allowable limits of system reactance and the importance of the concomitant shaft torques, some details are needed concerning shaft stresses since the stress is the quantity which must be limited, and system reactance is important only in its relation to the shaft stresses. The authors state that the American Standards on short circuits "serves to define the capability of the shaft with respect to the peak torque which may be applied." The writer agrees with this statement only in particular designs. The shear stress at the journals and adjacent shaft sections is the largest shear stress present except for concentrations, and these concentrations are of importance only in fatigue, which is not a major factor here. Yet this shear stress at the journals is quite small in comparison to the centrifugal stresses which are present throughout the rotor body, and an appreciable multiplying factor due to torsional resonance is needed before this shear stress gets dangerously high. In general, therefore, it is not a correct statement to say as the authors do that "The torque under this condition, then, is that for which the shaft is designed. . . . .". The shaft is designed for the centrifugal stresses in the rotor body, and only when the design is very close to torsional resonance must the shaft be designed around the torsional stresses.

In the particular example chosen by the authors, the writer would estimate that the nominal journal shear is of the order of 5,000 pounds per square inch, and with a multiplying factor of 3.25 as given in the paper, the journal shear stress is still below the centrifugal stresses in the rotor body, and this is true even when the shear stresses are converted to their equivalent tensile stresses. It should be noted that these centrifugal stresses are present whenever the machine is at rated speed whereas the shear stresses discussed here are present only during short circuits and reclosing operations. It is also true that there are several other operating conditions, such as simply clearing a fault, which would in some cases exceed this 3.25 times normal torque. The writer would appreciate it, therefore, if in the authors' reply they would give some numerical data about the actual shear stresses so that a quantitative evaluation can be made of the suggested limits of system reactance.

If the writer has been presumptuous, however, in assuming that the authors are making actual recommendations on system reactances, there is presented in the following a discussion of the paper on the basis of the explicit material contained therein. The study itself is very interesting, and illustrates the practical results which can be obtained on the electric-analog and similar computers. It is interesting to observe the degree by which mechanical computers are affecting design and operating engineering, and it is expected that when high-speed digital computers reach a reasonable cost that they will revolutionize our present engineering methods.

Figure 1. Single-cylinder turbine set

Figure 2. Tandem-compound, double-flow turbine set

Figure 3. Tandem-compound, triple-flow turbine set

Returning to the subject paper, it is disappointing that the authors did not study the reclosing shaft torques on a variety of machine designs rather than the single example which was chosen. The single-cylinder two-body design as presented in this paper and as shown in Figure 1 of this discussion is one of the simplest that is built by the Company with which this writer is associated. Furthermore, the machine chosen for an example in the subject paper is one which was relatively far from torsional resonance with the system.

As examples of other designs, the writer suggests the tandem-compound double-flow sets. These must be designed with considerable care to ensure that the torsional frequencies do not get too close to resonance with the system frequency. A diagram of such a 3-body system is shown in Figure 2 of this discussion. Each of the tandem-compound double-flow units built by the company with which this writer is associated is carefully analyzed to locate its torsional frequencies, and to keep such frequencies from resonance with the electrical system.

As an example of a design even more complex than the tandem-compound double-flow sets, the writer suggests the tandem-compound triple-flow set which was recently analyzed by the writer and his associates for torsional stresses during short circuits. This was a 5-body system such as is shown in Figure 3 of this discussion. The shear stresses in the shaft of this set were determined on our differential analyzer. Such an analyzer was necessary because of the complexity of the system.

In concluding this discussion on system reactances, the writer recommends a *single* limit on the minimum system reactance for reclosing operations rather than the two limits suggested in the subject paper. This single limit should be simply that the system reactance must be equal to or greater than the transient reactance of the machine.

Such a system reactance would limit the stator-winding stresses during reclosing to values less than those present during the ten-second short circuit defined in the standards. It should then be the responsibility of the manufacturer to ensure that the concomitant shaft torques would not result in dangerous shaft stresses. By Figure 8 of the subject paper, the crest shaft torque for the example chosen would then be about five times normal, and, if the writer's estimate of the nominal shear stress is reasonably close, the resulting crest shear stress is not dangerous from shaft stress considerations.

The writer believes that a single limit as recommended in this discussion would be a far more satisfactory arrangement than the double standard suggested in the subject paper.

The writer would also like to point out a discrepancy in the published data on the relative severity of a line-line fault from full load and a reclosing operation at 90 degrees out of phase for a system reactance equal to the generator subtransient reactance. Figure 7 of a paper by McCann, Warren, and Criner[1] indicates that the line-line fault from full load produces more severe shaft torques than the reclosing operation, for the conditions stated previously, for a 2-body system, especially so for a set with a low torsional frequency.

The subject paper presents the opposite conclusion, however, and states that the line-line fault from full load, for the example chosen by the authors, will have a crest torque of 4.35 times normal, but that reclosing the same machine 90 degrees out of phase with a system reactance equal to the generator subtransient reactance will produce a crest torque of about six times normal.

REFERENCE

1. See reference 5 of the paper.

M. D. Ross (Westinghouse Electric Corporation, East Pittsburgh, Pa.): The major emphasis in the paper is upon the possible damage to the generator due to excessive shaft torques. While the shaft may be considerably twisted due to bad out-of-phase synchronizing which upsets the balance of the unit, the damage to the stator may also be considerable. As few engineers ever see the damage to stator windings, I have picked out a typical illustration from the files as a matter of interest. Figure 4 of the discussion shows the damage to a 25,000-kva 1,800-rpm generator built about 20 years ago and would be typical of damage due to

Figure 4

excess current, whether from a short circuit or synchronizing out of phase. A superficial inspection of the picture shows nothing unusual but a close check will show the distorted coils at the junction between phase groups. In a case like this, it would be necessary to completely rewind the stator in order to put it in good shape.

Faulty synchronizing of machines happens very rarely and does not justify building into the generator the ability to stand such faulty operations without damage to the shaft or the windings. The cost of the generator would be greatly increased if it were found to be possible to make such a design. In such a case as we are considering here, where we deliberately synchronize out of phase, it is therefore important to carefully consider the stresses in the generator set up by such operation. This paper is a step in the direction of setting up limits which will safeguard the generator and the authors are to be congratulated on their very constructive paper.

J. W. Batchelor: It is possible that Rankin has misinterpreted the intent of the paper, which was to discuss shaft stresses produced by particular transients in the electrical system. In this case, the effect of centrifugal stress is not being considered. Centrifugal stresses and transient torsional stresses under fault conditions do not bear a fixed relationship to each other, since their separate magnitudes may be affected by various factors in the design of the unit. The figures in the paper apply to the particular unit which was under study, and do not necessarily apply to other units which must be designed to meet a wide variety of conditions.

The use of a single limit of external reactance equal to or greater than the transient reactance of the generator would provide ample margin in the large majority of cases of normal machines of present day proportions connected through reclosing tie-lines to high voltage transmission systems.

The reference to the apparent discrepancy between the subject paper and Figure 7 of the paper by McCann, Warren, and Criner[1] calls attention to the importance of the proper determination of system conditions at the moment of reclosure. The curves in the earlier paper were drawn for radically different machine proportions, as well as for different voltage and load conditions. Consequently, exact agreement is not to be expected.

Ross' comments and illustration demonstrate a problem which was only touched upon in the paper, but which is of interest to those who have system operating conditions requiring transmission line reclosing.

Arcing Fault Currents in Low-Voltage A-C Circuits

C. F. WAGNER
FELLOW AIEE

L. L. FOUNTAIN
MEMBER AIEE

THE recommended AIEE method[1] of calculating short-circuit currents in circuits of 600 volts and below is based upon the assumption of a "bolted" fault. Circuit breakers applied to such circuits are rated on the maximum value of the average rms currents in the three phases. The effect of dissymmetry is included by multiplying the symmetrical short-circuit current for the bolted-fault condition by the factor 1.25 which then gives the average current in the three phases. This corresponds to a short circuit in which maximum dissymmetry occurs in one phase, and the X/R ratio of the circuit is 11.8. The rms current in the phase of maximum dissymmetry is 1.48 times the rms symmetrical current. Some engineers believe that the fault current calculated upon the basis of a bolted fault is inordinately high and that such values are not obtained in practice. Whether this be true or not is dependent to a large extent upon the nature of the fault, upon how the faults are initiated, and upon the effect of the fault arc in limiting the short-circuit current.

In 1941, O. R. Schurig[2] presented data on the effect of fault voltage drops and impedances upon the short-circuit currents in low-voltage circuits. In his synopsis, the statement appears that "Instances are shown where actual fault currents reach 100 per cent of the rms symmetrical values calculated for bolted faults." In his conclusions, the following statement appears "The current-limiting effect of accidental arc faults in low-voltage bus structures may be of a minor order, arc fault currents as high as 88 and 100 per cent (average 3-phase values) of the rms symmetrical bolted-fault short-circuit current having been obtained in tests at 300 volts and 600 volts line-to-line, open-circuit voltage, respectively." These figures represent a reduction from the bolted-fault factor of 1.25 to an arcing fault factor of 0.88 or 1.0. Schurig in a footnote recognizes this effect as representing a reduction to 70 and 80 per cent for 300 and 600 volt circuits respectively as compared to a bolted fault.

Without attempting to specify the conditions under which various types of electrical apparatus should be applied to low voltage circuits, there appears to be a distinct need to clarify the situation insofar as the effect of arc drop is concerned. An investigation of this subject is in progress by the working group on calculating short circuit currents in low-voltage systems of AIEE switchgear committee. As a contribution to this activity, the Westinghouse Electric Corporation undertook the tests described in this paper. These tests were made in standard metal-enclosed bus structures, the short circuit being initiated by fusing copper wires and by metal objects resting across the bus conductors. Various sizes of fuse wire were used to determine what effect this might have upon the current. Naturally, as the size of the wire is increased, bolted-fault conditions are approached.

Description of Test

Figures 1*a* to 1*d* are illustrations of the conventional cubicle in which the faults were initiated. Standard bus construction and supports were used. The vertical 3-phase bus run in Figure 1*a* consists of $1/4 \times 4$ inch copper bars spaced four inches and the horizontal run $1/4 \times 6$ inch copper bars also spaced four inches. Figure 2 is a schematic diagram of the circuit used. Power was supplied from a 3-phase source through cables. The open circuit voltage of the circuits was adjusted to 500, 250, and 125 volts. As determined from the bolted-fault tests, the X/R ratio of the circuit was 11.8.

The circuit was adjusted approximately to give a "nominal" value of current. For each "nominal" setting, tests were made with a bolted fault. The "bolted fault" was made by clamping copper straps across the busses at the same point at which the fuse wire was connected. Figure 1*a* shows the fuse wire in position. Figure 1*a* also shows the metal bar used in certain tests to initiate the fault as it lay in position across the horizontal bus run. An oscillogram was taken of each short circuit.

Test Results

As is characteristic of arcs, the drop across it was found to be quite variable. The oscillogram of Figure 3*a* (Test 2-72956) is typical of this condition. As the arc drop is an appreciable fraction of the circuit voltage, the variations in the arc drop are reflected in the magnitude of the current, a large arc drop tending to produce a small current and a small arc drop, a large current. The arc in Figure 3*a* was initiated by a number 14 copper wire connection from phases 1 to 2 and phases 2 to 3. Figure 3*b* is an oscillogram of the short-circuit current for the same condition except that the fault is a bolted one.

To determine the first half-cycle values of current for the arcing fault, the peak current of the first significant half cycle in each of the three phases was measured. It was then assumed that these half cycles of current were of sinusoidal wave shape. These values and the average rms of the currents in the three phases are tabulated in Table I for the 500-volt circuit; and in

Paper 48-26, recommended by the AIEE industrial power systems; switchgear; and transmission and distribution committees and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted November 14, 1947; made available for printing, December 22, 1947.

C. F. WAGNER is manager, central station engineering department and L. L. FOUNTAIN is an electrical engineer, with the Westinghouse Electric Corporation, East Pittsburgh, Pa.

Figure 1. Conventional metal-clad switchgear cubicle used in tests

Figure 1B

Table II, for the 250-volt circuit. Two groups of tests were made several months apart. The division between the groups is indicated by the gap in the tables. In the tabulation of the single-phase tests the rms currents were expressed both in terms of the 3-phase bolted symmetrical current and the single-phase bolted symmetrical current. In comparing the arcing currents with the single-phase bolted symmetrical currents, it must be remembered that for a bolted single-phase short circuit the maximum rms current for a circuit whose X/R is 11.8 is

Figure 2. Schematic diagram of test circuit

Figure 3. Typical oscillograms

(b) (below, right). Bolted short circuit for same circuit condition as (a)

1.48 times the symmetrical current.

The average first half-cycle rms currents are also plotted in Figure 4 against the average bolted symmetrical rms current. In many of the tests, the arc extinguished and cleared the circuit before tripping of the circuit breaker which was set for a time of 10 cycles. To differentiate between the clearing and nonclearing points, the tests in which the arc was extinguished are indicated by open circles and those in which the arc hung on are indicated by blacked circles. All the 3-phase tests at 500 volts hung on and all the 250-volt tests both single-phase and 3-phase cleared without the circuit breaker opening. The results with single-phase 500 volts were mixed.

For a given condition of initiation, the ratio of the first half-cycle arcing current to the bolted-fault current generally decreases as the bolted-fault current is increased.

A large number of points were taken with the circuit impedances set to give 68,000 amperes and 78,600 amperes for the symmetrical bolted condition at 500 volts and to give 58,000 amperes at 250 volts. Different sizes of copper wire were used to initiate the faults. In Figure 5, the

Figure 4 (above). Average first half-cycle rms currents

Notations indicate size of copper wire used as fuse and other methods of initiating the fault. Open circles indicate that short circuit was self clearing

Figure 5. First half-cycle rms current as affected by nature of initiating means

(A) (B)

Figure 6. Oscillograms of 3-phase short circuit initiated by three number 8 copper wires connected across each of two pairs of busses at location shown in Figure 1A

Initial bolted symmetrical current is 57,100 amperes. Low voltage following initiation of short circuit denotes fusing period

results of the tests for these three conditions are plotted against the area of the shorting copper. The figures with the arrows indicate the magnitudes of the currents for the bolted-fault condition corresponding to the respective circuits. With very large wire, the fusing time becomes so long that bolted conditions are approached. As evidence of this condition, see Figure 6 (Test 2-74965). The low values of

Figure 7. Sustained current averaged over third to sixth cycles—500-volts circuit

voltage immediately after application of the voltage to the circuit indicates the time required for the development of the arc.

Likewise, in Figures 4 and 5 are plotted the first half-cycle values of current when the fault is initiated by a copper or steel bar resting across the busses. In Figure 5, these values are indicated by short heavy horizontal lines whose relations to the abscissa have no significance. In all cases, the bars were thrown from their positions violently. These values lie intermediate between the values obtained for small and for large wire. After a large number of tests, the interior of the structure and the insulators became covered with a finely divided conducting deposit. Some evidence of this coating may be seen in Figure 1*a* in which a portion had been rubbed off by the operator in connecting the fuse wires. The points in Figures 4 and 5 marked "insulator failure" represent flashovers of the insulator resulting from this deposit.

As stated previously, the arcing faults on the 250-volt tests were not sustained but cleared themselves. After the first two cycles on the 500-volt circuit, the transient effects associated with the initiating process appear to have disappeared. The currents thereafter are dependent upon the impedance of the circuit and the arc drop. To determine the nature of these effects, the peak currents were measured for both halves of the third to sixth cycles, inclusive. These values were then averaged and converted to rms values. The results are tabulated in Tables III and IV for the 3-phase and single-phase short circuits, respectively, and plotted in Figure 7. Both the 3-phase and the line-to-line arcing currents are plotted against the 3-phase bolted-fault currents. Only one value, and this 0.86, exceeded 0.8.

As another approach in determining the effect of the arc on limiting the current, the arc voltage was measured for each half cycle between the third and sixth cycles. The results of these measurements are

Figure 8. Arc voltage averaged over three phases—500-volt circuit

likewise tabulated in Tables III and IV and plotted in Figure 8. These values lie in general between 0.4 and 0.6 of the line voltage which in this case was 500 volts.

As a means of reflecting the effect of the arc drop upon the average rms current in the three phases, the curves in Figure 9 were computed. The abscissa expresses the arc drop as a per cent of the line voltage. The dotted lines and their continuation into the full lines give the symmetrical component of the current as a fraction of the symmetrical component of current with no arc (bolted fault) for three assumed ratios of reactance to resistance of the metallic portion of the circuit. The small circles on the dotted lines indicate the time constant of the circuit including the arc drop as a resistance drop. These in turn provide the medium to determine the extent by which the currents should be increased to include asymmetry. Since the arc drops for Figure 8 lie between 0.4 and 0.6 of the circuit voltage, the curves of Figure 9 for this range indicate that for the arcing fault condition, the average rms currents should lie between about 0.7 and 0.9 of the symmetrical current assuming that the fault developed into an arcing fault instantly.

Summary

1. On 250-volt and 125-volt a-c circuits, arcing faults are unstable and will extinguish themselves within two cycles or less even when initiated by four number 8 copper wires on a bus with 4-inch spacing. On

Figure 9. Effect of arc drop upon average rms current in three phases at end of first half cycle (including asymmetrical component)

Dotted line gives symmetrical component only.

Note: Nine other single-phase tests at 500 volts (see Table I) also made but current cleared within two cycles.

buses with less than 4-inch spacing, it would be expected that the arc would have more of a tendency to stabilize itself.

2. About half of the line-to-line arcing faults on the 500-volt circuit were unstable and extinguished themselves.

3. The magnitudes of the first-half-cycle values of current are dependent upon the means of initiating the fault. In using a relatively small wire for the initiating means, the current as compared to the bolted-fault current decreases as the circuit current level is increased. On the 500-volt circuits, the results of the copper bar and steel bar tests indicate that a factor of 0.9 might be applied to the bolted symmetrical current for systems whose bolted-fault currents are in excess of 40,000 amperes and a factor of 1.0 for systems whose bolted-fault currents are less than 40,000 amperes. On 250-volt circuits, the factor appears to be smaller.

4. On 500-volt circuits, the sustained currents may be less than 0.8 of the bolted symmetrical currents.

Discussion

R. S. Ferguson and J. Grotzinger (Goodyear Tire and Rubber Company, Akron, Ohio): After reading this paper the question arises, "Just what sort of fault do we seek protection against when we apply circuit breakers to low-voltage a-c circuits of 500 and 250 volts?" If we are seeking protection against the possibility of a bolted bus fault, whose occurrence may be very rare, the factor 1.25 times the symmetrical short circuit is in order.

The tests which are reported in this paper would seem to indicate that a factor which approaches 1.25, say 1.10, should be used if we are to protect against short circuits which might be caused by faulty connections in control wiring on 500-volt circuits, because the tests indicate a current for the first half cycle which is 1.10 times the symmetrical value. They also indicate that the arc does not clear itself. They do indicate that after the first half cycle the current decreases materially due to the arc impedance, and consequently the circuit breaker will be called upon to clear a considerably smaller value of current.

In the case of 250-volt circuits, a factor considerably less than 1.10 times symmetrical current may be applied, because the tests indicate that both single phase and 3-phase shorts are self-clearing. Whereas the circuit breaker may have to carry 1.10 times symmetrical short-circuit current for one cycle, it will not have to interrupt this current because the arc clears itself. The tests are interesting in that they indicate that a short circuit which is caused by accidentally placing a copper or steel bar across the 500-volt bus will be less than 0.9 times symmetrical short circuit current.

No data is presented to show what happens when a bar is placed across a 250-volt bus. The assumption may safely be made that here too the arc will be self-clearing because of the fact that the bar is thrown violently from its position.

Another interesting fact brought out by the tests is that an insulator flashover which is caused by a deposit of conducting material results in a short circuit of 0.7 times the symmetrical short-circuit current value.

One method of initiating the fault which is not covered by this extensive series of tests is one which we have often wondered about. In order to make these tests complete we think it would be valuable to obtain data on the magnitude of the short-circuit current which is obtained when we get a short circuit in a piece of equipment like a large motor or transformer.

A general conclusion that can be drawn from the facts which are covered by this paper is that a circuit breaker which has an interrupting capacity considerably less than the recommended practice may after all give adequate protection for practically all faults which it will ever be called upon to clear.

R. H. Kaufmann (General Electric Company, Schenectady, N. Y.): The test information reported in this paper constitutes valuable additional knowledge regarding actual fault current magnitude in the presence of arcing bus faults.

The practical significance of these results are judged to be:

1. Measured fault current magnitudes under arcing fault conditions at 250 and 500 volts alternating current in 4-inch spaced bus work closely approach the values predicted by analysis for solid bolted fault conditions.

Analysis (bolted fault), I = 1.25 times symmetrical component of bolted fault current

Observed in 250 volt tests, I = 1.17 times symmetrical component of bolted fault current

Observed in 500 volt tests, I = 1.08 times symmetrical component of bolted fault current

(Note if the arcing fault had occurred at or near cable terminals entering the switchgear structure, the spacing would be less than 4 inches and measured currents likely to be even closer to the bolted vault case)

2. Extends and confirms test data obtained by other investigators.

3. Strengthens the contention that present simplified analysis procedure yields the correct circuit breaker interrupting rating and no large factors of safety are implied even in the presence of arcing faults.

A word of caution relative to interpretation of the summary may be in order.

The test data reported pertains to arcing faults in 4-inch spaced bus work while the title of the paper is more general "Arcing Faults in Low-Voltage A-C Circuits."

Points 1 and 2 about the self-extinguishing character of the arc pertain only to the specific tests in 4-inch spaced bus work. Experience in 208/120 volt networks certainly proves that faults cannot be depended upon to be self-clearing. To lead a reader to the conclusion that faults on a-c circuits of 250 volts or less are self-clearing would be doing a great wrong.

In point 4, the statement that sustained currents may be less than 80 per cent of the bolted fault values as worded might lead to the interpretation that they will be consistently below the 80 per cent value which would be untrue. Circuit breakers obviously must be capable of safely handling the maximum fault current. To be able to safely handle the average fault condition is not enough.

D. L. Beeman (General Electric Company, Schenectady, N. Y.): This paper represents an extension of the work on the effect of arcs on short-circuit current magnitudes in a-c systems, 600 volts and less. It is always desirable to have valuable engineering information of this nature presented for those who wish to make use of it. The paper confirms two facts previously established:

1. That arcs in the short-circuit current path are very erratic in their effect on the total magnitude of short-circuit current.

2. That the arc is substantially like a resistance and thereby tends to reduce the X/R ratio of circuit and hence, the presence of an arc may reduce the magnitude of the d-c component.

Part 3 of the summary of this paper mentions that certain factors might be applied to the bolted-fault currents. This implies using these factors to determine short-circuit currents.

While anyone may use the information in this and other papers for calculating short-circuit currents it is felt that the adoption of this suggestion for general usage would not be advisable for the following reasons:

1. Years have been spent in getting engineers and others to recognize the short-circuit current problem in low-voltage a-c systems. It is still not recognized by the National Electrical Code (NEC) to the point where short-circuit currents are considered in the application of the Code nor is it considered properly in the rating of many protective devices, most notable of which are the NEC fuses. One of the greatest stumbling blocks in obtaining wider recognition of this problem in low-voltage circuit has been the complexity in short-circuit calculating procedures. The work of a former AIEE committee in simplifying these procedures was most helpful in the advancement of this phase of the art. This committee laid down the first simplified rules and they have been followed with pre-eminent success to date.

The addition of factors to account for an erratic phenomena like arc impedance would be a complexity which would tend to defeat the purpose of simplification and thereby tend to retard wider spread recognition on a sound engineering basis of the short-circuit problem in low-voltage circuits.

2. The present generalized procedure is based on assuming a bolted fault of zero impedance at the point of short-circuit. This was chosen because it has been proved by other tests and reiterated by this paper that the maximum available short-circuit current for any given circuit arrangement can be accurately determined if a bolted fault is assumed. When and only when the maximum short-circuit current is known can the user apply circuit protective device or other circuit elements and know that the maximum short-circuit current attainable is within the short-circuit rating of the equipment.

Field experience has also shown that bolted faults do occur, hence, the introduction of a reduction factor to account for arc drop in the general case seems unsound because:

1. It does not show the maximum short-circuit current as pointed out previously.

2. Arcs are so erratic in their behavior that it would be difficult to ever reach agreement as to just how much arc drop was to be taken into account in the general case. There is no disagreement on the procedure when considering bolted faults.

3. Any generalized calculating procedure which does not show maximum short-circuit current will lead to wide spread application of circuit breakers and other circuit equipment whose short-circuit current rating is less than the maximum fault current which can flow in that circuit. Hence, this will subject many installations to the hazards of inadequate circuit breakers, and so forth.

3. The information presented in the paper while valuable and useful to those who wish to study arc phenomena does not in any way detract from the desirability of maintaining the general case on the basis of the bolted fault which gives the maximum current. The general case which is on the basis of the bolted fault provides a means for the general engineering public to select circuit breakers that are fully adequate for any short circuit in a given system without using anything except the simplest rules. Yet, if anyone so desires he is free to use the data in this article or any other to assume any arbitrary reduction factors he sees fit to account for some phenomena that may not always be present in the circuit like arc resistance. When he does apply such arbitrary reduction factors and applies equipment whose short-circuit rating is less than the maximum short-circuit current attainable by a bolted fault, he is completely responsible for his acts should cases arise and equipment failures or injury to personnel result because of short-circuit currents being in excess of apparatus rating. It is interesting to note that the great majority of engineers prefer to apply circuit breakers in such a way that the maximum total short-circuit current available at the point of application of the circuit breaker as calculated by the general rules assuming a bolted fault is within the interrupting ratings of the circuit breaker.

W. J. McLachlan (General Electric Company, Schenectady, N. Y.): The data presented in this paper constitute a substantial addition to that presented by Schurig referred to by the authors. Variances in the results obtained in comparison to the Schurig data no doubt are related to differences in the conditions of the two sets of tests. However, variations in current values obtained in service experience will be much greater than the range of results reported in both of these papers due to the vastly wider range of conditions influencing the fault impedances in actual installations than is feasible to include in such testing programs. Such variable conditions include, among others, the phase-to-phase and phase-to-ground conductor clearances, the spacing to adjacent circuits, the type and confining influence of any enclosures and, particularly, the manner in which the fault is initiated.

With regard to the manner of fault initiation, it appears entirely probable that bolted-fault current values may be much more closely approached and even fully obtained where foreign objects inadvertently are placed in a bus structure in such manner as to not be free to "blow clear" of the conductors as was the case in both the Schurig and the subject paper tests. Such a result may obtain either through the object being wedged in the structure or through its being so placed that magnetic forces are in a direction to hold it against the conductors rather than in a repelling direction.

With such wide divergence between the possible conditions obtaining in actual service faults and the necessarily limited scope of these testing programs, together with the fact that actual equivalent bolted faults have occurred and will no doubt occur again, it is obvious that the criteria for completely safe applications must be the calculated "bolted-fault" currents. It should be clearly understood and recognized that application on the basis of lesser values involves definite risk.

C. F. Wagner and **L. L. Fountain:** Before replying to the discussions in detail we wish to emphasize a statement made in the paper that the primary purpose of these tests was to provide additional data for the use of the AIEE committee concerned with "Calculating Short-Circuit Currents in Low-Voltage Systems." This committee is being reorganized under the sponsorship of the switchgear committee with representation from the industrial power systems and the transmission and distribution committees. The question of recommending factors for use of the industry in applying circuit breakers in low-voltage circuits is entirely their prerogative and rightly so, as action of this character should be based upon the combined experience and information of the manufacturers, users and anyone else who may possess data pertinent to the problem. All are agreed that the factor 1.25 applied to the symmetrical component of the short-circuit current under bolted fault conditions gives a representative value of the rms current averaged over the three phases for this condition. However, these questions arise

"How can a fault of this character occur in service?";

"If the equivalent of bolted faults occur, what is the frequency of their occurrency?";

"Are all faults of the arcing type?"; or

"What is the nature of the current limiting effect of the arc?"

Thus the question of whether the factor 1.25 should be retained for all applications or whether it should be changed involves a matter of judgment in which factors of the foregoing character must be weighed. The present paper is concerned with the phenomena that occur in the presence of an arc. It attempts to shed light on this question and shows definitely that when an arc is involved the currents are significantly smaller than when the fault is bolted. It is hoped

that the committee will find the data presented in this paper of value in their deliberations.

We wish to thank Ferguson and Grotzinger for their discussion as it reflects the point of view of an industrial user. The discussions by Kaufmann, Beeman and McLachlan are largely concerned with upholding the sanctity of the "bolted fault" as a basis of application. We wish to object to the implication of Kaufmann's statement that the "measured fault current magnitudes under arcing fault conditions at 250 and 500 volts alternating current in 4-inch spaced buswork closely approach the values predicted by analysis for solid bolted fault conditions." He then refers to the factor 1.17 (should have been 1.11) for the 250-volt tests and 1.08 for the 500-volt tests. The conditions for which these factors apply are hardly representative arcing faults. By the method in which the tests were made one could get no other result than those indicated. As we continued to add more and more copper wire for the initiating means bolted-fault conditions were obviously approached. These factors in themselves have no significance. By adding still more copper we could easily have obtained factors of 1.15, 1.20 or even 1.25. The actual figure obtained is determined largely by the time required to fuse the wire. The fault initially is a bolted one and just here is where the matter of judgment enters again. Does the fusion of a metallic conductor bolted across the bus or a loose member resting across it represent more closely the condition met in practice?

When Kaufmann refers to the confirmation of tests by previous investigators he probably refers to the work of Schurig. We wish to call attention again to Schurig's data which indicate maximum factors of 0.88 and 1.0 instead of 1.25.

We certainly did not mean in point 4 of the summary that sustained currents would be consistently below 80 per cent of the bolted symmetrical currents and cannot understand how such interpretation could be placed upon the expression "may be less than 0.80."

Steady-State Equivalent Circuits of Synchronous and Induction Machines

GABRIEL KRON
MEMBER AIEE

Synopsis: Equivalent circuits are developed for the various types of salient-pole synchronous and asymmetrical induction machines, expressed along the physical direct and quadrature axes (cross-field theory). The torques again are found by a direct measurement of power. The networks of all types of machines are found as special cases of that of the "primitive" machine. All equivalent circuits along the physical axes are derivable from those along the hypothetical symmetrical component axes (revolving-field theory) by a real transformation. Although the latter types of networks have already been published previously, they are reproduced here for comparison with the new networks and for a unified tensorial treatment of rotating machines and their equivalent circuits.

The Two Basic Reference Frames

IN the theory of single, isolated rotating machines possessing no commutators two basic reference frames usually are assumed.

1. The axes are rigidly connected to the salient-pole structure.

2. Hypothetical "symmetrical component" axes are associated with the foregoing physical axes.

When rotating machines are interconnected with each other or with transmission lines and other stationary structures, additional physical reference frames must be resorted to. Such additional frames are for instance

3. The axes rotate with a speed different from that of the rotor.

4. The axes execute small oscillations superimposed upon a steady rotation.

5. There are angular displacements (constant or variable) between the various axes of the same frame.

With each of these physical axes hypothetical symmetrical component axes may be associated.

This paper restricts itself to the systematic development of the steady-state equivalent circuits of single machines when their equations are expressed along the first two types of axes. While the existence of equivalent circuits along the hypothetical symmetrical component axes are widely recognized, it is not so well appreciated that equivalent circuits of equal simplicity may be constructed for any machine along the more physical direct and quadrature axes.

a) THE PRIMITIVE SYNCHRONOUS MACHINE

b) THE PRIMITIVE INDUCTION MACHINE

Figure 1. The primitive rotating machine

The systematic treatment of the equivalent circuits of commutator machines will be based upon the present study and will form the subject matter of a future publication.

The Primitive Machine at Rest

It will be assumed that the equations and equivalent circuits of all machines may be derived as special cases of those of a "primitive" machine. In this machine:

1. One member has a salient pole and asymmetrical windings, the other member is smooth and has symmetrical windings.

2. Depending whether the salient pole is moving or stationary, two such "primitive" machines will be distinguished (Figure 1), namely, the "primitive synchronous" machine and the "primitive induction" machine. The equations and equivalent circuits of both types of primitive machines are identical, differing only by the sign of the speed term v and of the torque T.

3. There exist two independent sets of axes at right angles in space, one along the salient pole (direct axis d) and one at right angles to it (quadrature axis q).

4. Along each axis four windings are assumed, in particular two on the stator and two on the rotor.

When the machine is at rest, each axis may be represented by an arrangement of inductive coils representing the magnetic structure (Figure 2e). See also reference 4 for greater detail. The electrical structure is represented by the resistances and impressed voltages in series.

Equations of the Primitive Machine

The transient equations of the primitive induction machine are (reference 1, page 129) $e = Z \cdot i^1$ where Z is given in Figure 3.

For a synchronous machine $p\theta$ has opposite signs, the subscript s becomes f

Paper 48-27, recommended by the AIEE rotating machinery committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted September 5, 1947; made available for printing December 24, 1947.

GABRIEL KRON is consulting engineer, General Electric Company, Schenectady, N. Y.

Figure 3. Impedance matrix of the primitive machine (induction)

Figure 4. The primitive machine along symmetrical components

(field) and r becomes a (armature). To save space in further manipulations, this $\boldsymbol{Z}$ will be represented as a compound matrix

$$\boldsymbol{Z}=\begin{array}{c|cccc} & s_2 & s_1 & r_1 & r_2 \\ \hline s_2 & \boldsymbol{Z}_{s2} & \boldsymbol{X}_s & \boldsymbol{X}_{r12} & \boldsymbol{X}_{r22} \\ s_1 & \boldsymbol{X}_s & \boldsymbol{Z}_{s1} & \boldsymbol{X}_{r11} & \boldsymbol{X}_{r21} \\ r_1 & \boldsymbol{X}_{r12} & \boldsymbol{X}_{r11} & \boldsymbol{Z}_{r1} & \boldsymbol{X}_r \\ r_2 & \boldsymbol{X}_{r22} & \boldsymbol{X}_{r21} & \boldsymbol{X}_r & \boldsymbol{Z}_{r2} \end{array} \tag{1}$$

where each $\boldsymbol{Z}_r$ matrix has the form

$$\boldsymbol{Z}_r=\begin{array}{c|cc} & d_r & q_r \\ \hline d_r & r_r+L_{dr}p & L_{qr}p\theta \\ q_r & -L_{dr}p\theta & r_r+L_{qr}p \end{array} \tag{2}$$

The other matrices are special cases of $\boldsymbol{Z}_r$ and differ from it in the following manner:

1. The $\boldsymbol{X}$ matrices contain no r terms.
2. The matrices with a subscript s (stator) contain no $p\theta$ terms. The r's in them assume the same form as the L's.

Figure 5. The polyphase primitive machine

(a). Polyphase synchronous machine
(b). Polyphase induction machine

Torque = real of iB^*

Figure 6. Synchronous machines (forward and backward axes)

Torque = real of $i^f B_f^* + i^b B_b^*$

Similarly the impressed voltage vector is

$$\mathbf{e} = \begin{array}{|c|c|c|c|c|c|c|c|} \hline d_{s2} & q_{s2} & d_{s1} & q_{s1} & d_{r1} & q_{r1} & d_{r2} & q_{r2} \\ \hline e_{ds2} & e_{qs2} & e_{ds1} & e_{qs1} & e_{dr1} & e_{qr1} & e_{dr2} & e_{qr2} \\ \hline \end{array} \tag{3}$$

Represented as a compound matrix, it becomes

$$\mathbf{e} = \begin{array}{|c|c|c|c|} \hline s_2 & s_1 & r_1 & r_2 \\ \hline \mathbf{e}_{s2} & \mathbf{e}_{s1} & \mathbf{e}_{r1} & \mathbf{e}_{r2} \\ \hline \end{array} \tag{4}$$

where

$$\mathbf{e}_r = \begin{array}{|c|c|} \hline d_r & q_r \\ \hline e_{dr} & e_{qr} \\ \hline \end{array} \tag{5}$$

From now on whenever new reference frames will be introduced only this $\mathbf{Z}_r$ (and $\mathbf{e}_r$) matrices will be calculated. The $\mathbf{Z}_s$, $\mathbf{X}_r$, and $\mathbf{X}_s$ matrices will be special cases of $\mathbf{Z}_r$ and will differ from it as just indicated.

During steady state, when the frequency of currents in all axes is not fundamental frequency (unity) but some other frequency f, then in the transient $\mathbf{Z}$

1. p becomes $jf\omega$
2. $p\theta$ becomes $v\omega$
3. ωL and ωM become X

Accordingly $\mathbf{Z}_r$ of equation 2 becomes

$$\mathbf{Z}_r = \begin{array}{c|c|c|} & d_r & q_r \\ \hline d_r & r_r + jfX_{dr} & vX_{qr} \\ \hline q_r & -vX_{dr} & r_r + jfX_{qr} \\ \hline \end{array} \tag{6}$$

Equivalent Circuits Along Symmetrical Components

To bring the matrix $\mathbf{Z}$ of Figure 3 to symmetrical form two transformations are introduced in succession.

1. Symmetrical components are introduced by

$$\mathbf{C}_1 = \begin{array}{c|c|c|c|c|} & s_2 & s_1 & r_1 & r_2 \\ \hline s_2 & \mathbf{C}_s & & & \\ \hline s_1 & & \mathbf{C}_s & & \\ \hline r_1 & & & \mathbf{C}_s & \\ \hline r_2 & & & & \mathbf{C}_s \\ \hline \end{array} \tag{7}$$

where

$$\mathbf{C}_s = \frac{1}{\sqrt{2}} \begin{array}{c|c|c|} & f & b \\ \hline d & 1 & 1 \\ \hline q & -j & j \\ \hline \end{array} \tag{8}$$

As a result each $\mathbf{Z}$, $\mathbf{X}$, and $\mathbf{e}$ is transformed:

$$\mathbf{Z}_r' = \mathbf{C}_{s1}^* \mathbf{Z}_r \mathbf{C}_s \tag{9}$$
$$\mathbf{e}' = \mathbf{C}_{s1}^* \mathbf{e}$$

2. The frequency is reduced to unity by

$$\mathbf{n} = \begin{array}{c|c|c|c|c|} & s_2 & s_1 & r_1 & r_2 \\ \hline s_2 & \mathbf{n}_s & & & \\ \hline s_1 & & \mathbf{n}_s & & \\ \hline r_1 & & & \mathbf{n}_{r1} & \\ \hline r_2 & & & & \mathbf{n}_{r2} \\ \hline \end{array} \tag{10}$$

$$\mathbf{n}_r = \begin{array}{c|c|c|} & f_r' & b_r' \\ \hline f_r & f-v & \\ \hline b_r & & f+v \\ \hline \end{array} \tag{11}$$

As a result each $\mathbf{Z}$, $\mathbf{X}$, and $\mathbf{e}$ is multiplied a

$$\mathbf{Z}_r'' = \mathbf{n}_r^{-1} \mathbf{Z}_r' \tag{12}$$
$$\mathbf{e}'' = \mathbf{n}_r^{-1} \mathbf{e}' \tag{13}$$

Remembering that $\mathbf{n}_s$ contains no v, the final matrices are

$$\mathbf{Z}''_r = \begin{array}{c|c|c|} & f_r & b_r \\ \hline f_r & \dfrac{r_r}{f-v} + j\left(\dfrac{X_{dr}+X_{qr}}{2}\right) & j\left(\dfrac{X_{dr}-X_{qr}}{2}\right) \\ \hline b_r & j\left(\dfrac{X_{dr}-X_{qr}}{2}\right) & \dfrac{r_r}{f+v} + j\left(\dfrac{X_{dr}+X_{qr}}{2}\right) \\ \hline \end{array} \tag{14}$$

Figure 7. Synchronous machines (forward and backward axes). Field circuits are eliminated

Torque = real of $i^f B_f^* + i^b B_b^*$

$$e_r'' = \boxed{\frac{e_{dr}+je_{qr}}{\sqrt{2}(f-v)} \;\Big|\; \frac{e_{dr}-je_{qr}}{\sqrt{2}(f+v)}} \tag{15}$$

The corresponding equivalent circuits on the two primitive machines are shown on Figure 4. The torques are found by the product of the resultant rotor (or armature) currents i and fluxes E. When the machine structure is smooth, the windings are symmetrical and only polyphase currents and voltages exist, then $i^q = -ji^d$ and only the forward meshes exist. The corresponding polyphase primitive equivalent circuits are shown in Figure 5.

Actual Machines

The equivalent circuits of the various types of synchronous and induction machines shown on Figures 6–8 are special cases of the primitive machine and are found from the latter by simply opening certain meshes. These networks already have been published in references 1–4.

On synchronous machines it is customary to eliminate all field axes and consider only the armature axes. The corresponding simplified circuits are shown in Figure 7. Note that the phase displacement between the excitation and the infinite bus is still the angle δ. The capacitor motor differs from the primitive machine in two respects:

1. Its direction of rotation is from q to d, hence the f axis rotates also from q to d.
2. The ratio of turns on the q_s axis is a.

Equivalent Circuits Along Physical Axes

Once the equations of the primitive machine have been brought to a symmetrical form along some particular axes, it is comparatively easy to keep the symmetrical form along other arbitrary axes. A return to the original d and q axes may be accomplished in two successive steps

1. The inverse transformation C_s^{-1} returns to the original physical axes

$$C_s^{-1} = \frac{1}{\sqrt{2}} \begin{array}{c|cc} & d' & q' \\ \hline f & 1 & j \\ b & 1 & -j \end{array} \tag{16}$$

Figure 8 (below). Induction machines (revolving field theory)

Torque = real of $i^{fr} B_f^* + i^{br} B_b^*$

but the resultant $\boldsymbol{Z}$ is not quite symmetrical.

2. The latter may be brought to a symmetrical form by allowing js^q to flow in the network in place of i^q. That is, the additional transformation (changing the time scale in the network along the q axis) is

$$C_2 = \begin{array}{c|cc} & d & q \\ \hline d' & 1 & \\ q' & & -j \end{array} \tag{17}$$

The two transformations may be combined into one as

$$C_3 = C_1^{-1}C_2 = \frac{1}{\sqrt{2}} \begin{array}{c|cc} & d & q \\ \hline f & 1 & 1 \\ b & 1 & -1 \end{array} \tag{18}$$

Transforming $\boldsymbol{Z}_r''$ and $\boldsymbol{e}_r''$ of equations 14 and 15 as

$$\boldsymbol{Z}_r''' = C_{n1}^* \boldsymbol{Z}_r'' C_n \tag{19}$$

$$\boldsymbol{e}''' = C_{n1}^* \boldsymbol{e}'' \tag{20}$$

the resultant matrices are

$$\boldsymbol{Z}_r''' = \begin{array}{c|cc} & d & q \\ \hline d & \dfrac{fr_r}{f^2-v^2}+jd_{dr} & \dfrac{vr_r}{f^2-v^2} \\ q & \dfrac{vr_r}{f^2-v^2} & \dfrac{fr_r}{f^2-v^2}+jX_{qr} \end{array} \tag{21}$$

$$\boldsymbol{e}''' = \begin{array}{c|cc} & d & q \\ \hline & \dfrac{fe_{dr}+jve_{qr}}{f^2-v^2} & \dfrac{ve_{dr}+jfe_{qr}}{f^2-v^2} \end{array} \tag{22}$$

In setting up the resultant $\boldsymbol{Z}'''$ analogously to Figure 3 it should be remembered that

1. The $\boldsymbol{X}'''$ matrices contain no r terms.

2. The matrices with a subscript s contain no v terms.

The corresponding equivalent circuits of the two types of primitive machines are shown in Figure 9. For a polyphase machine (where $i^q = -ji^d$, hence $js^q = i^d$) the equivalent circuit reduces to the same form as that given for symmetrical components, Figure 5, since $i^f = \sqrt{2}\, i^d$. Hence on Figure 5 each i may be considered as representing either i^f or i^d. The same statement applies to e.

For the various types of synchronous and induction machines the equivalent circuits are given in Figures 10 through 12. It should be noted that

1. In the symmetrical component circuits (Figures 4–8) mutual couplings exist between the f and b axes for the *asymmetrical* member only.

2. In the physical circuits (Figures 9–12) mutual couplings exist between the d and q axes for the *symmetrical* member only.

Figure 9. The primitive machine along physical axes

Torque = real of $i^{dr} B_q^* + (ji^{qr})(jB_d)^*$

Summary of Transformations

1. In considering the equations of actual rotating machines it is possible to pass from the physical d and q axes to the hypothetical f and b axes and back again by the transformation C_r and its inverse

$$C_r = \frac{1}{\sqrt{2}} \begin{array}{c|cc} & f & b \\ \hline d & 1 & 1 \\ q & -j & j \end{array}$$

$$C_r^{-1} = \frac{1}{\sqrt{2}} \begin{array}{c|cc} & d & q \\ \hline f & 1 & j \\ b & 1 & -j \end{array} \qquad (23)$$

2. In considering the equations not of actual machines but of their equivalent circuits, it is possible to pass from the physical d and q axes to the hypothetical f and b axes and back again by the transformation C_n (Equation 18) and its inverse

$$C_n = \frac{1}{\sqrt{2}} \begin{array}{c|cc} & f & b \\ \hline d & 1 & 1 \\ q & 1 & -1 \end{array}$$

$$C_n^{-1} = \frac{1}{\sqrt{2}} \begin{array}{c|cc} & d & q \\ \hline f & 1 & 1 \\ b & 1 & -1 \end{array} \qquad (24)$$

Hence, just as all actual rotating machines form a "group" (allowing to pass from the equations of any one machine to that of any other machine by means of a nonsingular C) similarly their equivalent circuits also form a group and it is possible to pass from the equation of any one equivalent circuit to that of any other by means of a C.

Transformations Between Machines and Their Equivalent Circuits

Having shown that all rotating machines form a "group" and that all their equivalent circuits form another group, the question arises in what relations are the two groups to each other.

It may be said in general that while the same currents flow in a machine and in its equivalent circuit, nevertheless different voltages are impressed on them. That is, in going from the equations of a machine to its equivalent circuit the voltages are transformed by $n^{-1} = n_m^{-1}$, but the currents are not. If the subscript m represents a machine and n a network then

$$\left.\begin{aligned} e_n &= n^{-1} e_m \\ e_{\alpha'} &= n_{\alpha'} e_\alpha \end{aligned}\right\} \qquad (25)$$

$$\left.\begin{aligned} Z_n &= n^{-1} Z_m \\ Z_{\alpha'\beta} &= n_{\alpha'}^{\alpha} Z_{\alpha\beta} \end{aligned}\right\} \qquad (26)$$

and the equations of a machine and its equivalent circuit are, respectively,

$$\left.\begin{aligned} e_m &= Z_m i \\ e_\alpha &= Z_{\alpha\beta} i^\beta \end{aligned}\right\} \qquad (27)$$

$$\left.\begin{aligned} e_n &= Z_n i = n^{-1} Z_m i \\ e_{\alpha'} &= Z_{\alpha'\beta} i^\beta \end{aligned}\right\} \qquad (28)$$

Hence the tensors of the group of equivalent circuits are "intermediary tensors" having their indices in two different refer-

ence frames and the two groups are simply subgroups of a more extended group.

The transformation matrices $n = n_n^n$ changing from the network to its machine and back again are as follows:

1. When expressed along symmetrical components

$$n_s = \begin{array}{c|cc|} & f_m & b_m \\ \hline f_n & f-v & \\ b_n & & f+v \\ \hline \end{array}$$

$$n_s^{-1} = \begin{array}{c|cc|} & f_n & b_n \\ \hline f_m & 1/(f-v) & \\ b_m & & 1/(f+v) \\ \hline \end{array} \tag{29}$$

2. When expressed along the physical direct and quadrature axes

$$n_p = C_s n_s C_s^{-1} \tag{30}$$

$$n_p = \begin{array}{c|cc|} & d_m & q_m \\ \hline d_n & f & -jv \\ q_n & jv & f \\ \hline \end{array}$$

$$n_p^{-1} = \frac{1}{f^2 - v^2} \begin{array}{c|cc|} & d_n & q_n \\ \hline d_m & f & jv \\ q_m & -jv & f \\ \hline \end{array} \tag{31}$$

It has to be remembered, though, that at first the time axis of $\bar{s}^n$ in the network equations has to be changed by j as shown in equation 17 before n_p may be used.

No Discussion

An Induction Generator Used With the All-Electric Automatic Pilot for Airplanes

HERBERT VICKERS
FELLOW AIEE

THIS PAPER deals with the theory of a special type of induction generator from which two demands are made:

(*a*). The voltage in the signal phase must be linearly proportional to the speed at which it is driven.

(*b*). The phase angle between the signal voltage and the reference voltage must not change more than a small fraction of a degree over the speed range.

The machine consists of a stator with slotted core, which accommodates two phases—one is the reference phase, which is supplied with alternating current at a frequency of 400 cycles, and the other phase, in quadrature with the reference phase, is the phase from which the signal voltage is derived. The rotor consists of a conducting sleeve or squirrel cage with a fixed iron core. The requirements (*a*) and (*b*) are met, as will be shown in the analysis, by using a high resistance rotor, and also the leakage fluxes of stator and rotor must be kept small.

The method of attack is briefly as follows:

1. The axis of the reference phase is designated as the X axis.
2. The axis of the signal phase is designated as the Y axis.
3. The flux along the signal phase axis is calculated in terms of the flux along the reference axis.

The real problem is that laid down in item 3. It will be found to involve a linear differential equation of the second order of standard type, whose solution furnishes us with the information we need to attain our desired results.

The reference phase of the stator produces flux only along its axis, namely, the X axis, it is clear that the flux linking the signal phase in the Y axis, can be furnished only by rotor currents. We must therefore find the magnetomotive forces along the X axis in stator and rotor, and also the magnetomotive forces along the Y axis in both rotor and stator.

Consider a coil AB on the rotor, the plane of which makes an angle θ with the X axis at any time t.

Let

ϕ_c = resolved part of the flux in the direction of the coil axis

Then

$$\phi_c = \phi_{RX} \sin\theta - \phi_{RY} \cos\theta \tag{1}$$

where

$$\phi_{RX} = \text{flux in the rotor along the } X \text{ axis} \tag{2}$$

$$\phi_{RY} = \text{flux in the rotor along the } Y \text{ axis} \tag{3}$$

The electromotive force induced in the coil AB, due to variation of ϕ_{RX} and ϕ_{RY} with time and also due to variation of θ with time, is obtained by differentiating equation 1 with regard to time.

$$\phi_c' = \omega \cos\theta\phi_{RX} + \omega \sin\theta\phi_{RY} + \sin\theta\phi_{RX}' - \cos\theta\phi_{RY}' \tag{4}$$

where

$\omega = d\theta/dt$.

Paper 48-28, recommended by the AIEE rotating machinery committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted September 16, 1946; made available for printing December 5, 1947.

HERBERT VICKERS is consultant with Smith Electric Company, Cricklewood, London, England and Clarke, Chapman and Company, Gateshead on Tyne, England.

The author wishes to acknowledge his debt to F. W. Meredith for his help in this problem.

The current in the coil is

$$-\phi_c'/r10^8 \tag{5}$$

where r is the resistance of the coil in ohms; the coil is assumed to have one turn.

The magnetomotive force of the coil is

$$0.4\pi i_c \tag{6}$$

which equals $\mathfrak{F}_c$. Therefore

$$\mathfrak{F}_c = (-4\pi/10^8 r)(\omega\phi_{RX} \cos\theta - \phi_{RY}' \cos\theta + \omega\phi_{RY} \sin\theta + \phi_{RX}' \sin\theta) \tag{7}$$

The resolved part of $\mathfrak{F}_c$ along the X axis, which we may call

$$\delta\mathfrak{F}_{RX} = (-4\pi/10^8 r)(\omega\phi_{RX} \sin\theta \cos\theta - \phi_{RY}' \sin\theta \cos\theta + \omega\phi_{RY} \sin^2\theta + \phi_{RX}' \sin^2\theta) \tag{8}$$

To find the total magnetomotive along the X axis, due to N_2 coils or $2N_2$ rotor bars, we must sum up the magnetomotive forces due to these N_2 coils along the X axis. Therefore

$$\mathfrak{F}_{RX} = (-4\pi/10^8 r)(N_2 \int_0^\pi \sin^2\theta\{\omega\phi_{RY} + \phi_{RX}'\} + \cos\theta \sin\theta\{\omega\phi_{RX} - \phi_{RY}'\} d\theta/\pi \tag{9}$$

$$= -2\pi N_2\{\omega\phi_{RY} + \phi_{RX}'\}/10^8 r \tag{10}$$

Determination of the Magnetomotive Force Along the Y Axis of the Rotor

The resolved part of $\mathfrak{F}_c$ along the Y axis of the rotor is

$$\delta\mathfrak{F}_{RY} = (-4\pi/10^8 r)(-\omega\phi_{RX} \cos^2\theta + \cos^2\theta\phi_{RY}' - \omega\phi_{RY} \sin\theta \cos\theta - \phi_{RX}' \sin\theta \cos\theta) \tag{11}$$

Summing up the resolved parts of the magnetomotive forces along the Y axis for the N_2 coils on the rotor, we have

$$\mathfrak{F}_{RY} = (2\pi N_2/10^8 r)(\omega\phi_{RX} - \phi_{RY}') \tag{12}$$

Let

$$k_2 = 2\pi N_2/10^8 r \tag{13}$$

Then

$$\mathfrak{F}_{RY} = k_2\omega\phi_{RX} - k_2\phi_{RY}' \tag{14}$$

$$\mathfrak{F}_{RX} = -k_2\omega\phi_{RY} - k_2\phi_{RX}' \tag{15}$$

Let

R = air-gap reluctance

and

$$\alpha = R/k_2 = 10^9 rR/2\pi N_2 \tag{16}$$

Equations 14 and 15 enable us to obtain the relation between ϕ_{SY} and ϕ_{SX} which we need. The derivation is given in Appendix I.

The result is

$$\phi_{SY} = \omega\phi_{SXM} \sin(\omega_0 t - \lambda) / \sqrt{\left[\{(1+\sigma_r)k_2(\sigma_r+\sigma_r\sigma_s+\sigma_s)/R\} \times \{\omega^3-\omega_0^3\} + R(1+\sigma_s)/k_2\right]^2 + [1+2\sigma_r+2\sigma_s+2\sigma_r\sigma_s]^2\omega_0^2} \tag{17}$$

$$\tan\lambda = (1+2\sigma_r+2\sigma_s+2\sigma_r\sigma_s)\omega_0 / \{(1+\sigma_r)k_2(\sigma_r+\sigma_r\sigma_s+\sigma_s)/R\}\{\omega^3-\omega_0^3\} + R(1+\sigma_s)/k_2 \tag{18}$$

ϕ_{SXM} = maximum value of the flux in the X axis of the stator

λ = angle of lag of ϕ_{SY} behind ϕ_{SX}

ω = angular velocity of the rotor in radians per second

$\omega_0 = 2\pi \times$ supply frequency

$\sigma_r = RP_r$ = leakage flux in rotor ÷ useful flux in rotor

$\sigma_s = RP_s$ = leakage flux in stator ÷ useful flux in stator in X axis

Equation 17 shows that ϕ_{SY}, which is the flux in the signal axis, is nearly proportional to the speed, and the more nearly so as the term involving ω in the denominator is negligibly small.

This will be so provided

$$k_2/R = 1/\alpha = 2\pi N_2/10^9 rR$$

is small. Clearly r must be large and also R must be as large as is permissible. A high resistance rotor is, therefore, necessary, and the air-gap reluctance must be as great as the heating limits permit. Since, also, the phase shift of ϕ_{SY} with respect to ϕ_{SX}, as the speed varies, also must be very small, equation 18 shows that the same condition must be satisfied as for the first requirement, that is, that ϕ_{SY} shall be proportional to the speed.

It is clear from equation 18 that tan λ will be sensibly independent of the speed, provided k_2 is small, that is, provided we have a high resistance rotor.

Results of Investigation

Our investigation shows that we need some material for the rotor having high resistivity and low temperature coefficient. Generators have been built having Eureka bars and brass end rings, but successful results have also been achieved by using a high resistance sleeve of German silver or brass.

Very accurate centering of the rotor is necessary, and the thickness of the cylinder or sleeve must be quite uniform. Also, it is desirable to keep the leakage fluxes in stator and rotor small.

Formulas for $\mathfrak{F}_{SX}$, $\mathfrak{F}_{RX}$, ϕ_{SX}, E_{SY}, and I_S

In order to determine completely the characteristics of such a generator, we need to obtain expressions for the magnetomotive forces $\mathfrak{F}_{SX}$ and $\mathfrak{F}_{RX}$, and also for ϕ_{SX} and the signal voltage E_{SY} and the stator current.

All these quantities are calculated in the appendixes, and we merely will give the results here.

The procedure is to calculate $\mathfrak{F}_{SX}$ and $\mathfrak{F}_{RX}$ in terms of ϕ_{SX} and then to determine ϕ_{SX} from the voltage and frequency applied to the machine and its known winding data.

From $\mathfrak{F}_{SX}$ and $\mathfrak{F}_{RX}$ the stator and rotor currents are readily determined, and also the various phase angles of these quantities. Knowing ϕ_{SY}, one can determine the number of turns per coil required on the signal axis.

$$\mathfrak{F}_{SX} = [-k_2\omega(1+\sigma_r) - RD/\omega - k_2(1+\sigma_r)D^3/\omega]\phi_{SY} \tag{19}$$

ϕ_{SY} is given in equation 17. By substituting the value given in equation 17 for ϕ_{SY} and operating on it by the three terms in the bracket, we obtain $\mathfrak{F}_{RX}$

$$\mathfrak{F}_{SX} = (R/\omega)([(1+2\sigma_r)(\omega^3+D^3)/\alpha + 2D(1+\sigma_r)+\alpha])\phi_{SY} \tag{20}$$

Formula for ϕ_{SX}

$$v = \phi_{SXM} \times k \sin(\omega_0 t + \delta) \tag{21}$$

$$\phi_{SXM} = V_m/k$$

where

N_s = number of turns in series in signal phase

k_1 = breadth factor for the fundamental

k_4 = coil-span factor for the fundamental

$$E_{SX} = \sqrt{2}\pi \times k_1 k_4 \phi_{SYM} \times N_s \times f/10^8 \tag{22}$$

where

k_4 = coil span factor for fundamental

f = supply frequency

The current is determined from the magnetomotive force by equation 61 as follows:

$$\mathfrak{F}_{SXM} = 1.8 N_1 \times k_1 \times k_4 \times I/p \tag{23}$$

It is clear that this method can be applied to the calculation of single-phase induction motors. Its application is simple and direct, and much shorter than would seem from the analysis.

Appendix I

Proof of Equation 17 for ϕ_{SY} in Terms of ϕ_{SX}

From equations 14 and 15

$$\mathfrak{F}_{RY} = k_2\omega\phi_{RX} - k_2\phi_{RY}' \tag{14}$$

Figure 1. Derivation of the magnetomotive force in the X axis of the rotor

$$\mathfrak{F}_{RX} = -k_2\omega\phi_{RY} - k_2\phi_{RX}' \tag{15}$$

$$\phi_{RX} = \phi_{SX} - \phi_{LX} \tag{24}$$

ϕ_{LX} = stator plus rotor leakage flux in the X axis

$$= \mathfrak{F}_{SX}P_{SX} - \mathfrak{F}_{RX}P_{RX} \tag{25}$$

P_{SX} = equivalent permeance of stator leakage path (26)

P_{RX} = equivalent permeance of rotor leakage path (27)

$$\mathfrak{F}_{RY} = k_2\omega[\phi_{SX} - \mathfrak{F}_{SX}P_{SX} + \mathfrak{F}_{RX}P_{RX}] - k_2\phi_{RY}' \tag{28}$$

$$\phi_{RY} = \phi_{SY} + \mathfrak{F}_{RY}P_{RY} = \phi_{SY} + \mathfrak{F}_{RY}P_{RX} \tag{29}$$

This simply states that the rotor flux in the Y axis is the sum of the stator flux in the Y axis plus the rotor leakage flux in the Y axis. Therefore

$$\phi_{RY} = \mathfrak{F}_{RY}/R + \mathfrak{F}_{RY}P_{RX} = \mathfrak{F}_{RY}[1+RP_{RX}]/R = \mathfrak{F}_{RY}(1+\sigma_r)/R \tag{30}$$

$$\phi_{RY}R/(1+\sigma_r) = k_2\omega[\phi_{SX} - P_{SX}(R\phi_{SX} - \mathfrak{F}_{RX})/(1+\sigma_s) + \mathfrak{F}_{RX}P_{RX}] - k_2\phi_{RY}' \tag{31}$$

for

$$\phi_{SX} = (\mathfrak{F}_{SX} - \mathfrak{F}_{RX})(1+\sigma_s)/R \tag{32}$$

$$\phi_{RY}R/(1+\sigma_r) = k_2\omega\phi_{SX}/(1+\sigma_s) + \{k_2\omega\sigma_r/R + k_2\omega\sigma_s/R(1+\sigma_s)\}\{-k_2\omega\phi_{RY} - k_2\phi_{RX}'\} - k_2\phi_{RY}' \tag{33}$$

This step will be clear, if we remember that

$$P_{SX}R = \sigma_s$$

and

$$P_{RX}R = \sigma_r$$

Therefore

$$\phi_{RY}R/(1+\sigma_r) = A\phi_{SX} - B\phi_{RY} - C\phi_{RX}' - k_2\phi_{RY}' \tag{34}$$

$$A = k_2\omega/(1+\sigma_s) \tag{35}$$

$$B = k_2\omega[k_2\omega\sigma_r/R + k_2\omega\sigma_s/R(1+\sigma_s)] \tag{36}$$

$$C = B/\omega \tag{37}$$

Now substitute the value of ϕ_{RX}' derived from equation 14

$$\phi_{RX} = \mathfrak{F}_{RY}/k_2\omega + \phi_{RY}'/\omega \tag{38}$$

$$= \phi_{RY}R/(1+\sigma_r)k_2\omega + \phi_{RY}'/\omega \tag{39}$$

Therefore

$$\phi_{RX}'' = \phi_{RY}'R/(1+\sigma_r)(k_2\omega) + \phi_{RY}''/\omega \quad (40)$$

$$A\phi_{SX} = C\phi_{RY}''/\omega + \phi_{RY}'\{CR/k_2\omega(1+\sigma_r) + k_2\}+(\phi_{RY}R)/(1+\sigma_r) + B\phi_{RY} \quad (41)$$

$$\phi_{XY} = A\omega\phi_{SX}/CD^2 + \{k_2\omega + CR/k_2(1+\sigma_r)\} D + R\omega/(1+\sigma_R) + B\omega \quad (42)$$

where

$$D = d/dt + D^2 = d^2/dt^2 \quad (43)$$

Now

$$C/A = k_2\{\sigma_r + \sigma_r\sigma_s + \sigma_s\}/R \quad (44)$$

and

$$B/A = k_2\omega\{\sigma_r + \sigma_r\sigma_s + \sigma_s\}/R \quad (45)$$

but

$$\phi_{SY} = \phi_{RY}/(1+\sigma_r) \quad (46)$$

Therefore

$$\phi_{SY} = \omega\phi_{SXM}\sin(\omega_0 t - \lambda)/\times \sqrt{[\{(1+\sigma_r)k_2(\sigma_r+\sigma_r\sigma_s+\sigma_s)/R\}\{\omega^2 - \omega_0^2\} + R(1+\sigma_s)/k_2]^2 + [1+2\sigma_r + 2\sigma_s + 2\sigma_r\sigma_s]^2\omega_0^2} \quad (47)$$

and

$$\tan\lambda = (1+2\sigma_r+2\sigma_s+2\sigma_r\sigma_s)\omega_0/\{(1+\sigma_r)k_2(\sigma_r+\sigma_r\sigma_s+\sigma_s)/R\}\{\omega^2-\omega_0^2\} + R(1+\sigma_s)/k_2 \quad (48)$$

If one neglects the products and squares of ρ_r and ρ_s one obtains

$$\phi_{SY} \cong \omega\phi_{SXM}\sin(\omega_0 t - \lambda)/ \sqrt{[\{(\sigma_r+\sigma_s)(\omega^2-\omega_0^2)/\alpha\} + \alpha(1+\sigma_s)]^2 + [1+2\sigma_r+2\sigma_s]^2\omega_0^2} \quad (49)$$

Figure 2. Vector diagram for machine

E_s = counterelectromotive force induced in the stator reference phase by ϕ_{SX}

$DE = R_s I_s$ = volts drop in the external resistance to bring supply volts in line with the signal volts

This diagram shows the phase relations of the various quantities. ϕ_{SY}, F_{SX}, F_{RX}, I_s are all determined with reference to ϕ_{SX}, and ϕ_{SX} is then determined with reference to the applied volts

All these quantities and their phase angles are determined from the various equations for them given in the appendixes

and

$$\tan\lambda \cong (1+2\sigma_r+2\sigma_s)\omega_0/\{(\sigma_r+\sigma_s)(\omega^2-\omega_0^2)/\alpha\} + \alpha(1+\sigma_s) \quad (50)$$

Appendix II

Determination of the Magnetomotive Force in the X Axis of the Rotor $\mathfrak{F}_{RX}$

From equation 15

$$\mathfrak{F}_{RX} = -k_2\omega\phi_{RY} - k_2\phi_{RX}'$$

where

$$\phi_{RX}' = d/dt(\phi_{RX})$$

$$\mathfrak{F}_{RX} = -k_2\omega\phi_{RY} - k_2[\mathfrak{F}_{RY}' + k_2\phi_{RY}'']/k_2\omega \quad (51)$$

$$= -k_2\omega\phi_{RY} - R\phi_{SY}'/\omega - k_2\phi_{RY}''/\omega \quad (52)$$

since

$$\mathfrak{F}ry' = \phi_{SY}'R$$

$$\mathfrak{F}_{RX} = -k_2\omega(1+\sigma_r)\phi_{SY} - R\phi_{SY}'/\omega - k_2(1+\sigma_r)\phi_{SY}''/\omega \quad (53)$$

$$= [-k_2\omega(1+\sigma_r) - RD/\omega - k_2(1+\sigma_r)D^2/\omega]\phi_{SY} \quad (54)$$

We already have obtained ϕ_{SY} in terms of ϕ_{SX} and thus $\mathfrak{F}_{RX}$ is obtained by operating on ϕ_{SY} (expressed in terms of ϕ_{SX} by equation 47) by the factor in square brackets.

Equation 52 also may be expressed thus

$$\mathfrak{F}_{RX} = [-R\omega^2(1+\sigma_r)/\alpha - RD - R(1+\sigma_r)\times D^2/\alpha]\phi_{SXM}\sin(\omega_0 t - \alpha)/ \sqrt{(\ )^2 + (\ )^2} \quad (55)$$

Appendix III

Determination of $\mathfrak{F}_{SX}$, the Magnetomotive Force in the X Axis of the Stator

$$\phi_{SX} = \{(\mathfrak{F}_{SX} + \mathfrak{F}_{RX})/R\} + \mathfrak{F}_{SX}P_{SX} \quad (56)$$

that is, the total flux in the X axis of the stator is equal to the flux in the X axis which crosses the air gap, plus the stator leakage flux.

$\mathfrak{F}_{RX}$ will be negative in any numerical example. It is the component of the rotor magnetomotive force measured in the positive direction of the X axis.

$$\mathfrak{F}_{SX} = (R\phi_{SX} - F_{RX})/(1+\sigma_s) \quad (57)$$

since

$$RP_{SX} = \sigma_s$$

but

$$\phi_{SX} = [\{(1+\sigma_r)(\sigma_r+\sigma_r\sigma_s+\sigma_s)/\alpha\} + D^2] + D(1+2\sigma_r+2\sigma_r\sigma_s+2\sigma_r\sigma_s) + \alpha(1+\sigma_s)]\phi_{SY}/\omega \quad (58)$$

and

$$\mathfrak{F}_{RX} = R[(\omega^2+D^2)(2\sigma_r+1)/\alpha + 2D(1+\sigma_r) + \alpha]\phi_{SY}/\omega \quad (59)$$

Therefore

$$\mathfrak{F}_{SX} = R[(\omega^2+D^2)(2\sigma_r+1)/\alpha + 2D(1+\sigma_r) + \alpha]\phi_{SXM}\sin(\omega_0 t - \lambda)/\sqrt{(\ )^2 + (\ )^2} \quad (60)$$

$$\mathfrak{F}_{RX} = R[-\omega^2(1+\sigma_r)/\alpha - D - (1+\sigma_r)D^2/\alpha]\phi_{SY}/\omega \quad (61)$$

$$\mathfrak{F}_{SX} = R[(\omega^2+D^2)(1+2\sigma_r)/\alpha + 2D(1+\sigma_r) + \alpha]\phi_{SXM}\sin(\omega_0 t - \alpha)/ \sqrt{(\ )^2 + (\ )^2} \quad (62)$$

Thus the magnetomotive force is obtained by operating on ϕ_{SY} (which is expressed in terms of ϕ_{SX}) by the operator to the left.

Appendix IV

Determination of ϕ_{SX} in Terms of the Applied Voltage

Let

$$v = V_m \sin(\omega_0 t + \delta)$$

be the instantaneous value of the applied volts.

ϕ_{SX} is the reference vector, and V_m leads ϕ_{SX} by the angle δ

Then

$$v = N_1\phi_{SX}'k_1k_2/10^8 + R_s i \quad (63)$$

N_1 = number of turns in stator reference phase

k_1 = breadth factor of the stator winding for the fundamental

k_2 = coil span factor

For a single-phase winding, the amplitude of the magnetomotive force wave in ampere-turns is

$$\mathfrak{F}_{SXM} = 1.8N_1k_1k_2I/p \quad (64)$$

p = number of poles

R_s = resistance of reference phase

I = rms value of current in reference phase

Now $\mathfrak{F}_{SX}$ will be obtained in the form

$$a\phi_{SXM}\sin(\omega_0 t + \beta) \quad (65)$$

Therefore

$$v = N_1k_2k_1\omega_0\phi_{SXM}\cos\omega_0 t/10^8 + R_s a\phi_{SXM}\sin(\omega_0 t + \beta)/1.8N_1k_1k_2/p \quad (66)$$

Let

$$c = N_1k_1k_2\omega_0/10^8 \quad (67)$$

and

$$d = R_s a/(1.8N_1k_1k_2/p) \quad (68)$$

then

$$v = c\phi_{SXM}\cos\omega_0 t + d\phi_{SXM}\sin(\omega_0 t + \beta) \quad (69)$$

$$= c\phi_{SXM}\cos\omega_0 t + d\phi_{SXM}\sin\omega_0 t\cos\beta + d\phi_{SXM}\cos\omega_0 t\sin\beta \quad (70)$$

$$= \phi_{SXM}[(c + d\sin\beta)\cos\omega_0 t + d\cos\beta\times\sin\omega_0 t] \quad (71)$$

$$= \phi_{SXM}[f\cos\omega_0 t + g\sin\omega_0 t] \quad (72)$$

$$f = c + d\sin\beta \quad (73)$$

$$g = d\cos\beta \quad (74)$$

then

$$v = \phi_{SXM}k\sin(\omega_0 t + \delta) \quad (75)$$

where

$$k\cos\delta = g \quad (76)$$

and

$$k \sin \delta = f \tag{77}$$

$$k = \sqrt{g^2+f^2} \tag{78}$$

and

$$\tan \delta = f/g \tag{79}$$

Therefore

$$k = \sqrt{d^2 \cos^2 \beta + c^2 + 2cd \sin \beta + d^2 \sin^2 \beta} \tag{80}$$

$$= \sqrt{c^2+d^2+2cd \sin \beta} \tag{81}$$

and

$$\tan \delta = (c+d \sin \beta)/d \cos \beta \tag{82}$$

Now

$$V_m = \phi_{SXM} \times k \tag{83}$$

Therefore

$$\phi_{SXM} = V_m/k = V_m/\sqrt{c^2+d^2+2cd \sin \beta} \tag{84}$$

From equation 82 we can find the amplitude of ϕ_{SX} in terms of the amplitude of applied volts, namely, V_m, and also the phase angle δ from equation 77 between V_m and ϕ_{SX}.

Appendix V. List of Symbols

ϕ_{SX} = flux in the stator in the X axis

Single-Phase Synchronous Machine

I. A. TERRY
FELLOW AIEE

B. L. ROBERTSON
FELLOW AIEE

Introduction

THIS PAPER describes the theory of the performance of single-phase synchronous machines and presents test results in verification of the theory. The material in the paper is based upon work done by the authors quite a number of years ago, and is presented as an extension of the use of the two-reaction theory of analysis of synchronous-machine performance.

Synchronous machines in central stations, in industrial plants, and in general commercial use, are primarily three-phase. There are, however, a number of applications of synchronous machines, both as motors and generators, in which single-phase power is used quite advantageously. The outstanding illustrations lie in the fields of railway electrification and high-frequency heating where single-phase synchronous machines have a great importance. There are a number of railway applications which have been in use for many years, and more locomotives have been added recently in some of these applications. The authors believe that the fundamental nature of the analysis in the paper will produce a better understanding of the performance of single-phase machines, will fill a gap in the present published literature on synchronous machines, and hence make the paper of permanent value.

Types of single-phase power and single-phase synchronous machines in commercial use are considered first. Following this there is given a theoretical analysis of single-phase synchronous machines. In this analysis steady-state conditions are considered first, based on the classical assumption of no saturation and no stator hysteresis or eddy-current losses, treating the machine generally as a three-phase machine with direct and quadrature axes of symmetry and with one phase winding left idle. Considerations are also given to the effects of sudden changes in loading, sudden changes in circuit, starting performance, and load losses.

Types of Single-Phase Power and Synchronous Machines

The most important and perhaps the largest kilowatt usage of single-phase power is in railway electrification. There are a number of installations which have been in service for many years. Other uses of commercial-frequency single-phase power from 25 to 60 cycles are confined principally to small isolated plants, and for testing facilities.

The use of polyphase power for major railway electrification has been limited because of the complicated mechanical arrangements necessary for two high-voltage trolley wires instead of one, and the resultant high cost. Major electrifications have been 11,000-volt single-phase trolleys with step-down transformers to series-type 25-cycle traction motors. Another important installation uses a system that includes a single-phase motor-generator set on the locomotive. This consists of a high-voltage single-phase synchronous motor driving a d-c generator. Electric power is conducted from the generator to the d-c traction motors. One of the important advantages of this motor-generator system, from the viewpoint of power generation and transmission, is the power-factor correction obtainable from an over-excited synchronous motor.

There are three general methods of providing 25-cycle single-phase power to the railway trolleys. One is by means of a frequency-converter set operating from a 60-cycle system. This type of installation has resulted because existing 60-cycle power stations have been called upon to furnish relatively large blocks of single-phase power. Another method is the use of single-phase, 25-cycle, vertical waterwheel-driven generators or by the use of single-phase steam-turbine-driven generators. Important installations of both of these power sources are in operation. A third method of obtaining single-phase power is to take it directly from a polyphase system of the same frequency and accept the resulting unbalance if the system will stand it, or correct the unbalance by means of a phase converter. The phase converter is similar in operation to a condenser except that it furnishes negative-sequence current instead of positive-sequence current to the system. With it, perfect balance of the three-phase system may not be obtainable under all conditions of load and at all points, but a relatively large three-phase system as compared with the single-phase load can frequently be balanced near enough for practical purposes. It is understood that one foreign railway company is embarking currently on light branch-line electrification using a single-phase, 50-cycle trolley voltage which is derived from the commercial, 50-cycle, 3-phase power supply system without frequency changers.

There is in commercial operation a variation of this phase-converter system. Twenty-five-cycle single-phase power is taken from the trolley to a polyphase transformer bank on the locomotive to which is connected a three-phase induction motor operating as a phase balancer. The three-phase traction motors receive their power from this transformer-balancer system.

In addition to the use of single-phase power for railroads there are a few low-frequency applications and a number of high-frequency applications.

The use of low-frequency power is confined almost entirely to induction fur-

Paper 48-29, recommended by the AIEE rotating machinery committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26-30, 1948. Manuscript submitted November 17, 1947; made available for printing December 29, 1947.

Figure 1 (left). Two-pole diagram of synchronous machine

Figure 2. Vector diagram for single-phase machine

naces, but this type of furnace is rapidly becoming obsolete. In such apparatus the frequency is usually 15 cycles per second or less. The furnace is of the core type utilizing the principle of high flux density and a low rate of change of density to obtain the desired heating effects. The power factor of such a system is low, usually four-tenths to five-tenths, so that from the standpoint of kilovolt-ampere–kilowatt efficiency the scheme is rather uneconomical. The cost of static condensers to improve the power factor would be entirely prohibitive at such a low frequency.

There are two general uses of high-frequency single-phase power. One is for testing; for this, sine-wave generators usually supply the power, principally for testing cables, static capacitors, insulators, and some turn testing of electric machinery coils. The other application is to high-frequency induction furnaces. This type of furnace utilizes the principle of low flux density and high rate of change of density. The power factor is inherently lower than in low-frequency applications but, because of the high frequency, static condensers can be used to very good advantage.

A third use of high-frequency single-phase power is for the carrier-current supply for radio and similar purposes.

Design Features of Single-Phase Synchronous Machines

Low-frequency and usual commercial-frequency single-phase machines are of salient-pole construction. High-frequency sine-wave machines usually have cylindrical-rotor construction with a single-layer or double-layer type of field winding. The high-frequency machines for supplying power for induction furnaces sometimes have salient poles, and sometimes are of the inductor type. The very high-frequency machines used for carrier current are of the inductor type. In a polyphase system the power flows at a constant rate. In a single-phase system the power pulsates at twice line frequency. In a synchronous machine the single-phase current can be considered as pulsating at line frequency or it can be considered as comprising two rotating components, one rotating at synchronous speed in the forward direction and the other rotating at synchronous speed in the backward direction. The backward-rotating component induces twice-line-frequency currents into the rotor causing rotor heating which is well known as the limiting design feature of single-phase machines. All single-phase units, therefore, require amortisseur-winding effects to provide a low-resistance path for the induced currents. The higher the specific armature loading of the machine the larger in proportion the amortisseur-winding effect must be. For this reason, salient-pole machines are equipped with pole-face windings. As a result of skin effect the resistance of a bar imbedded in iron increases with the frequency and with the bar diameter. Therefore, the resistance is not inversely proportional to the area and there is a size beyond which it is practically useless to increase the diameter of a bar unless means are adopted for obtaining uniform current distribution from top to bottom. This has been accomplished in some cases by using transposed amortisseur-winding bars.

Cylindrical-rotor machines have pole-face windings consisting of conducting wedges electrically connected at the machine ends. In addition, sections of the field winding can be short-circuited to obtain still lower resistance to the backward-moving field.

High-frequency salient-pole machines show very good amortisseur characteristics in the main field winding alone, hence no rotor bar winding is provided. Further, skin effect would render such a winding quite inoperative. Inductor-type high-frequency alternators depend upon stray leakage paths for the necessary rotor-current damping. Because the number of poles is large, a very small mechanical angular oscillation will generate the necessary amortisseur-winding effect.

As the power in a single-phase system pulsates, the torque on the machine rotor and stator also pulsates. This impresses variable forces upon the supporting structure. In large units these forces are so great that it is necessary to provide an elastic or spring mounting between the frame and the foundation to eliminate excessive fatigue stresses. Except in very small machines the rotor inertia is so large that no speed variations due to the pulsating torque are discernible.

The starting performance of a single-phase synchronous motor severely limits its application. With single phase there is no net forward torque developed at standstill although there may be forward torque as soon as rotation commences. This increases with speed so that from above 40 per cent normal speed there is frequently enough net torque to continue the acceleration. Split-phase starting has been used with some degree of success, particularly in induction motors, but with the usual type of starting equipment consisting of a resistance and a reactance with no capacitor. The torque efficiency in this case is only about one-third that of the similar three-phase motor. By using a capacitor the torque efficiency can be materially increased, and with recent capacitor developments this has become a standard commercial practice in very small sizes, particularly with induction motors. One method used in motor-generator sets for railway service is to provide a starting motor to bring the set above half speed after which the single-phase power is supplied to the synchronous motor and the set attains synchro-

Figure 3. Excitation diagram for single-phase machine

$e=1$, $i=0.577$, $x_d=1.61$, $x_q=0.92$, $x_2=0.194$, 0.7 power factor

nism. Another method that has been used in some cases is to connect the d-c generator as a series motor for starting.

Single-phase generators are usually simply three-phase Y-connected machines with suitable rotor construction and one of the stator phases left idle. The idle phase may be considered as an insurance or protection in case of injury to one of the active phases. The reliability of present-day apparatus has reduced the emergency value of the additional phase, so some machines have been manufactured leaving out the third phase with consequent savings in cost.

Analysis of the Single-Phase Synchronous Machine

Basic assumptions underlying the general treatment already have been stated. The machines considered are of the salient-pole type having axes of symmetry at the pole centers and also midway between the poles, thus giving rise to direct and quadrature components of current, voltage, flux, and reactance. Further, the armature winding is assumed to be sinusoidally distributed, thereby fulfilling the conditions for the "ideal" synchronous machine. It is to be understood that the magnitudes of all quantities are expressed in per-unit terms.

The method of symmetrical components can be used to analyze the single-phase machine and to obtain correct results when harmonic voltages and currents are neglected. However, with different impedances in the two axes, a more detailed analysis appears necessary. The flux-linkage equations previously developed[1] for the three-phase machine completely define the operation of that type, and since the same equations are immediately adaptable to the single-phase machine the treatment here is based on them.

Vector Diagram—Excitation and Torque-Angle Characteristics

The analysis by way of flux linkages is carried through in Appendix 1 and is based upon the general two-pole machine shown in Figure 1. From equation 21 of that development one may draw the vector diagram for the single-phase machine, Figure 2. The diagram includes armature resistance, although it often can be neglected because it is small compared with the synchronous reactances. The third-harmonic voltage of equation 21 is not included in the diagram. Figure 2 thus corresponds exactly to that deduced by the method of symmetrical components.

The vector diagram represents a generator supplying a lagging current. All quantities have been divided by $\sqrt{3}$, the terminal voltage, e, being measured from line to neutral. It should be pointed out that the voltage drops are induced quantities, as shown by the direction of the arrows, and conform to equation 21 from which the figure is obtained. When treated as components of the terminal voltage the arrows on the resistance and reactance drops would be reversed. It is in this latter manner that they are usually regarded.

For the purpose of calculating the excitation, the vector diagram corresponding to cylindrical-rotor construction may be used. With usual values of voltage, current, power factor, and machine constants,[2] this form of diagram gives an excitation very close to that obtained when considering the actual effects of the salient poles.

Figure 3 shows the excitation diagram for the single-phase machine in terms of that for an equivalent cylindrical rotor, the construction of the diagram being similar in steps to that for the three-phase machine. Point m divides the total synchronous reactance drop, ea, which is $i\,(x_d+x_2)$ for the single-phase cylindrical-rotor machine, in the ratio $(x_q+x_2)/(x_d+x_2)$.[3] The projection of the excitation vector, oa, on the line om extended gives the excitation ob for the salient-pole machine.

Using the particular machine constants accompanying Figure 3, $oa=1.89$ and $ob=1.87$. With unity power factor, the excitation for the same machine as a cylindrical-rotor generator is 1.45 as against 1.41 from the salient-pole diagram. At leading power factors the difference becomes greater, being about ten per cent at 0.707 power factor leading.

From the preceding voltage expressions of Appendix 1, or perhaps better from the vector diagram of Figure 2

$$\begin{aligned} e_d &= e\cos\delta + 2i_{q1}r + i_{d1}(x_d+x_2) \\ e_q &= -e\sin\delta - 2i_{d1}r + i_{q1}(x_q+x_2) \end{aligned} \qquad (1)$$

Neglecting armature resistance, these quantities may be solved simultaneously for the currents which are

$$i_{d1} = \frac{e_d - e\cos\delta}{x_d+x_2}$$

and

$$i_{q1} = \frac{e_q + e\sin\delta}{x_q+x_2} \qquad (2)$$

The power output of the machine is

$$P = \frac{ee_d}{x_d+x_2}\sin\delta + \frac{ee_q}{x_q+x_2}\cos\delta + \frac{e^2(x_d-x_q)}{2(x_d+x_2)(x_q+x_2)}\sin 2\delta \qquad (3)$$

Figure 4. Power-angle characteristics of a single-phase motor

Figure 5. Equivalent circuits of a single-phase synchronous machine with one rotor circuit in each axis

a. Direct-axis circuit
b. Quadrature-axis circuit

Under steady-state operation e_q is zero, hence only the first and last terms of the foregoing power equation become significant. The procedure here is that shown by Doherty and Nickle.[3] As pointed out by them, the first term of the equation is that which would be obtained by cylindrical-rotor theory. The third term of the preceding equation, however, which signifies reluctance power, is due entirely to the salient-pole construction of the machine and is independent of any excitation on the rotor.

Figure 4 shows the power-angle curve for a typical single-phase salient-pole machine. The ordinate scale is power expressed in per unit of the three-phase rating, and the abscissa is the angle δ measured in electrical degrees. The machine is the same one discussed in reference to Figure 3, the constants of which are shown on the diagram. Maximum power is obtained from the preceding general equation by setting $dP/d\delta=0$, solving for δ and then substituting it in the power expression.

Figure 4 has been obtained from the equation

$$P=1.04 \sin \delta+0.172 \sin 2\delta \qquad (4)$$

with $e_d=1.87$ and $e=1.0$. It will be observed that the second term in the power equation is significant in magnitude, and affects considerably the pull-out angle of the machine although it increases the pull-out power only about five per cent. For the constants given the pull-out angle is approximately 74 electrical degrees.

The machine from which the constants were taken is rated 21,500-kva single phase, the current corresponding to 37,200-kva 3-phase. Normal power output is 15,000-kw at 0.7 power factor, and the normal torque angle therefore is 17.2 electrical degrees. Using the 3-phase base, the pull-out power is 2.68 times the normal single-phase load.

The load angle, δ, in terms of the load and the machine constants can be expressed by the relation

$$\delta=\tan^{-1}\frac{i(x_q+x_2)\cos\phi}{\sqrt{3}e+i(x_q+x_2)\sin\phi} \qquad (5)$$

Figure 2 is useful in the derivation. Neglecting armature resistance in load-angle analyses for very large machines introduces an error generally of less than one per cent, but resistance may not usually be disregarded when treating with small machines.

Figure 6. Three-phase acceleration current and torque curves of 500-kva 750-rpm 2,300-volt 25-cycle single-phase synchronous motor. Field short-circuited through discharge resistor

Data taken at reduced voltage and referred to normal. Dotted portion of curve to left of slip = 1 calculated from equivalent circuit

Sudden Change of Load

It is of usual occurrence that a machine operating under steady load conditions and corresponding rotor displacement suddenly undergoes a change in load. Such action is equivalent to shifting the rotor suddenly to a different angle. The load may be increased or decreased, but it is generally of more interest to know the machine performance under the first condition because of the importance of the new position with respect to breakdown torque.

When the machine finally has come back to steady-state operation it is of course also back on its steady-state power-angle curve, excitation and terminal voltage remaining constant. During the transient period, however, the machine follows a power-angle curve which is different from that of steady-state operation, and the torque at the new displacement angle will therefore be different from what it would be at the same angle under steady-state conditions.

For any given machine there is obviously a power-angle characteristic for each value of excitation and for each value of terminal voltage. This is shown by previous equations. From any one of these steady-state characteristics there will be any number of deviations to new power-angle relations, the deviation depending upon the amount of sudden load change.

The analysis for such conditions of operation for the three-phase machine has been given by Doherty and Nickle[4] and by Park.[5] For the single-phase machine

it remains merely to follow the same general treatment, remembering that the reactances now are modified by the addition of the negative-sequence reactance, x_2, as indicated in the development in this paper. If these substitutions of reactance are made, the value of synchronizing torque, T_{s1}, for sudden load change, with the machine running at an initial angle δ', is found to be

$$T_{s1}=\frac{ee_d'}{x_d+x_2}\cos\delta'+e^2\frac{(x_d-x_q)}{(x_d+x_2)(x_q+x_2)}\times\cos 2\delta'+e^2\frac{(x_d-x_d'')}{(x_d''+x_2)(x_d+x_2)}\sin^2\delta'+e^2\frac{(x_q-x_q'')}{(x_q+x_2)(x_q''+x_2)}\cos^2\delta' \quad (6)$$

The first two foregoing terms are seen to be the synchronizing torque at the angle δ' under steady-state operation, that is, the slope of the steady-state torque-angle curve.

Change of Circuit

It may happen that a three-phase machine has one of its lines opened so that it must care for its load by single-phase operation. With the machine terminal voltage, excitation, and load remaining constant, it is of interest to know the effect upon power angle, power factor, and line current due to the change in machine circuit. It is, of course, evident that the case of constant load is only one of several conditions of operation that might be imposed upon the machine, but since it is the usual case met in practice it is the one discussed here.

The steady-state power angle can be obtained easily for both the three-phase and the single-phase machine from the power-angle equations. The first has been presented previously,[3] and that for the single-phase machine is given in this paper. The excitation, e_d, is computed for the three-phase machine, assuming a cylindrical rotor, for a given power factor. It remains constant.

Knowing, then, the value of δ, its trigonometric functions can be substituted in the power-factor relation for the single-phase machine and the new power factor obtained. The ratio of the inphase component of current to the total current is the power factor, from Figure 2, resistance neglected,

$$\text{power factor}=\frac{i_{d1}\sin\delta+i_{q1}\cos\delta}{i/\sqrt{3}}=\frac{\frac{e_d-e\cos\delta}{(x_d+x_2)}\sin\delta+\frac{e\sin\delta}{(x_q+x_2)}\cos\delta}{\sqrt{\left(\frac{e_d-e\cos\delta}{(x_d+x_2)}\right)^2+\left(\frac{e\sin\delta}{(x_q+x_2)}\right)^2}} \quad (7)$$

Figure 7. Calculated single-phase acceleration current, rotor input, and torque

Field short-circuited through discharge resistor. Data taken at reduced voltage and referred to normal. Dotted portion of curve to left of slip = 1 calculated from equivalent circuit

With the power, power factor, and voltage now known, the single-phase line current follows immediately.

The power-angle relations for the machine previously mentioned are, single phase and three phase, respectively,

$$P_1=1.04\sin\delta+0.172\sin 2\delta,\ e_d=1.87 \quad (8)$$
$$P_3=1.17\sin\delta+0.233\sin 2\delta,\ e_d=1.87$$

For a power output of 15,000 kw at 0.7-power factor lagging (0.405 per-unit power)

$\delta_1=17.2$ electrical degrees
$\delta_3=14.5$ electrical degrees

respectively, and the power factors are

$pf_1=0.7$
$pf_3=0.645$

respectively.

A second illustration is furnished by a general-purpose three-phase motor having constants $x_d=0.8$, $x_q=0.44$, $x_2=0.15$, $e=1$, and 0.8 load. The machine was assumed to be running under three-phase conditions when one lead was opened, and the steady-state values obtained are given in Table I.

It will be noted that the single-phase power factors do not vary to any great extent from those of the three-phase cases. This is accounted for by the fact that the negative-sequence reactance is the only quantity causing any difference between

the power-factor expressions, and, in general, x_2 is not very large. The positive-sequence component of the single-phase current will therefore be approximately equal in magnitude to the three-phase line current. It can thus be said that, in general, the line current will rise to a value close to 1.73 times the initial line current when a three-phase machine has one lead opened while operating with constant load, excitation, and terminal voltage.

Starting Performance

The starting performance of a single-phase machine is calculated by means of the equivalent circuits representing the direct and quadrature axes, as has been presented [5,6] for the three-phase machine, except that the circuits are more involved. The equivalent circuits must satisfy the following conditions as set forth in equation 21: First, at standstill and with $\sqrt{3}e$ applied line-to-line, the current that flows is determined by the reactances $2x_d''/\sqrt{3}$ for the direct axis, and $2x_q''/\sqrt{3}$ for the quadrature axis. Second, at synchronism these reactances become $(x_d+x_2)/\sqrt{3}$ and $(x_q+x_2)/\sqrt{3}$, respectively.

From physical reasoning the following conditions must be satisfied. First, at any speed the armature copper loss is two-thirds of that due to the same current for 3-phase operation. Second, the impedance must be the same at the same positive or negative speed. Third, the currents in the rotor circuits must consist of two components, one at slip frequency, sf, and the other at the frequency $(2-s)f$. Fourth, the rotor currents are proportional to $i/\sqrt{3}$, whereas in the 3-phase machine they are proportional to i. Fifth, the starting torque is zero at standstill. In a machine having unequal impedances in the two major axes, the statements of the third and fourth conditions are not strictly complete since there are forward- and backward-moving magnetomotive forces of the rotor currents due to both the positive- and negative-sequence armature currents. The conditions involve the assumption, which is realized quite closely in single-phase machines except at small values of slip, that the backward-moving fields of the positive- and negative-sequence stator currents are zero.

The equivalent circuits that must satisfy the several conditions noted herein for the direct and quadrature axes of the single-phase machine with one rotor circuit only in each axis are shown in Figure 5. The line current is i, and $i/\sqrt{3}$ is the magnitude of the forward- and backward-moving current systems given in equation 12 of Appendix I. The rotor resistance and reactance are r_r and x_r, respectively. The analysis of starting performance from the equivalent circuits is given in Appendix II.

To determine the accuracy of the theory, test data were taken on two different single-phase motors with direct-connected d-c generators. The test data consisted of acceleration-torque information both single and 3-phase, open- and short-circuit core-loss measurements, and windage and friction curves. The 3-phase torque and current data are shown plotted in Figures 6 and 8. The projections to the left of the $s=1$ axis were calculated from test results for equivalent circuits that checked the tests at slips less than unity. Figures 7 and 9 shows the calculated and test curves for single-phase acceleration. The calculated curves were obtained from the relations that $s(z_{AD}+z_{AQ})/2$ holds for current and torque at slip s, and $(2-s)(z_{AD}+z_{AQ})/2$ holds for current and torque at slip $2-s$.

Figure 9. Calculated single-phase acceleration current, rotor input, and torque curves of 1,200-kva 750-rpm 2,300-volt 25-cycle single-phase synchronous motor, field short-circuited through discharge resistor

Test points indicated by dots

Load Loss

Under single-phase operation the load loss may be several times that under 3-phase operation with the same power output. This is due to the backward-rotating field, and so can be determined from it. If the squirrel-cage resistance is large, most of the load loss then will be in it. To give a definite check on the theory when iron or other stray losses are negligible, tests were made on an 8,250-kva 360-rpm 60-cycle motor with amortisseur bars having a resistance 25 times that of copper. The machine was driven at rated speed with backward rotation of the air-gap flux produced by a three-phase applied voltage. Under these conditions the input to the driving motor in excess of the windage, friction, and other constant losses equals the input to the set. Single-phase short-circuit core-loss tests also were taken. The results are shown in Figure 10.

Relations When Harmonic Currents Flow

The preceding analyses are based upon the assumption that only fundamental currents and voltages exist. This is fulfilled in machines designed especially for single-phase operation. However, in cases of unbalanced operation of some 3-phase machines, and in testing them for negative-sequence reactance, harmonics may appear. It is desirable to know the magnitude of these harmonics.

The currents under sustained single-phase short-circuit conditions can be written in the form

$$i_a = i_n \cos nt$$

$$= \sum \frac{i_n}{\sqrt{3}}[\cos(nt-30)+\cos(nt+30)] \quad (9)$$

Corresponding equations for the currents i_b and i_c would follow as in Appendix I. The first term in the brackets is the positive-sequence component and the second is the negative-sequence component. However, with the exception of the case in which $n=1$, the currents all will be

varying with respect to the rotor. A marked simplification results then by assuming that the reactance to nonfundamental currents is the same for a positively-rotating system as for one rotating negatively. The fundamental components when $n=1$ will meet synchronous and subtransient reactances according to whether they are of positive-sequence or negative-sequence character. The values of i_n are in geometric ratio when resistance is neglected, and the results apply for an external reactance as well as for a short circuit by making the appropriate allowance in the internal reactances. The analysis is similar to that for fundamental currents only, except that each current harmonic produces three voltages, one of its own harmonic order, one two orders lower, and one two orders higher. Thus the third-harmonic current produces fundamental, third-, and fifth-harmonic components in the terminal voltage.

The maximum ratio between harmonics is $(\sqrt{x_d''}-\sqrt{x_d''})/(\sqrt{x_q''}+\sqrt{x_d''})$. If $x_d''=x_q''$, the ratio is, of course, zero. For machines with x_d'' different from x_q'' by not more than 15 per cent, the harmonics are negligible for usual analyses.

Appendix I. Steady-State Voltage Equation With Fundamental Currents Flowing

The 2-pole synchronous machine is shown in Figure 1. Based on it the expression for the per-unit flux linkages of phase a of an ideal 3-phase machine has been given[1] by

$$\psi_a = e_d \cos\theta - e_q \sin\theta - \frac{x_0}{3}(i_a+i_b+i_c) - \frac{x_d+x_q}{3}\left(i_a-\frac{i_b+i_c}{2}\right) - \frac{x_d-x_q}{3}[i_a\cos 2\theta + i_b\cos(2\theta-120) + i_c\cos(2\theta+120)] \quad (10)$$

The corresponding expressions for the linkages of phases b and c are stated in a similar manner. Only positive-sequence currents are considered.

The single-phase machine, due to its method of construction, may be treated as a 3-phase machine with one phase left idle in operation, hence the single-phase armature currents are

$$i_a = i\cos t$$
$$i_b = -i_a = -i\cos t \quad (11)$$
$$i_c = 0$$

These currents can be resolved into their positive- and negative-sequence components, and hence become

$$i_a = i\cos t = \frac{i}{\sqrt{3}}[\cos(t-30)+\cos(t+30)]$$
$$i_b = -i\cos t = \frac{i}{\sqrt{3}}[\cos(t-150)+\cos(t+150)]$$
$$i_c = 0 = \frac{i}{\sqrt{3}}[\cos(t+90)+\cos(t-90)] \quad (12)$$

The first trigonometric function of each of these three current expressions form the positive-sequence system, the last set of three terms forming the negative-sequence group. The positive-sequence components of current meet with the synchronous reactances when the rotor is moving normally, and the negative-sequence components meet with the subtransient reactances which are to be denoted by double primes. The appropriate factor is therefore to be used with each type of current.

Substituting the last three relations for the single-phase currents in the linkage expression previously given, the single-phase flux linkages for phase a are

$$\psi_a = e_d\cos\theta - e_q\sin\theta - \frac{i}{\sqrt{3}}\left[\frac{x_d+x_q}{2}\times\cos(t-30)+\frac{x_d-x_q}{2}\cos(t+2\theta_0+30)+\frac{x_d''+x_q''}{2}\cos(t+30)+\frac{x_d''-x_q''}{2}\cos(3t+2\theta_0+30)\right] \quad (13)$$

The flux-linkage equations for phases b and c are obtained similarly.

The resultant voltage of each armature phase is equal to the time rate of change of flux linkages of that circuit minus the armature resistance drop. Hence, for phase a,

$$e_a = p\psi_a - ir = -e_q\cos\theta - e_d\sin\theta + \frac{i}{\sqrt{3}}\left[\frac{x_d+x_q}{2}\sin(t-30)+\frac{x_d-x_q}{2}\sin(t+2\theta_0+30)+x_2\sin(t+30)+3\left(\frac{x_d''-x_q''}{2}\right)\times\sin(3t+2\theta_0+30)\right]-ir\cos t \quad (14)$$

It will be noticed that x_2 has replaced the term $(x_d''+x_q'')/2$ which is the negative-sequence reactance of the machine when connected to a system through a large external impedance. The resistance drop for phase b becomes a positive quantity because $i_b=-i_a=-i$ in magnitude. The resistance drop for phase c is of course zero.

The line-to-line voltage under consideration is the difference between the voltages of phases a and b, hence

$$e_a-e_b = -\sqrt{3}e_d\sin(\theta+30)-\sqrt{3}e_q\cos(\theta+30)+i\left[\frac{x_d+x_q}{2}\sin t+\frac{x_d-x_q}{2}\sin(t+2\theta_0+60)+x_2\sin t+3\left(\frac{x_d''-x_q''}{2}\right)\sin(3t+2\theta_0+60)\right]-2ir\cos t$$
$$= -\sqrt{3}e_d\sin(\theta+30)-\sqrt{3}e_q\times\cos(\theta+30)+i\Big[x_d\sin(\theta+30)\times\cos(\theta_0+30)-x_q\cos(\theta+30)\times\sin(\theta_0+30)+x_2\sin(\theta+30)\cos(\theta_0+30)-x_2\cos(\theta+30)\sin(\theta_0+30)+3\left(\frac{x_d''-x_q''}{2}\right)\sin(3t+2\theta_0+60)-2r\cos(\theta+30)\cos(\theta_0+30)-2r\times\sin(\theta+30)\sin(\theta_0+30)\Big] \quad (15)$$

Figure 10. Single-phase armature current in per unit of normal 3-phase current

Thus far the armature currents have been expressed in terms of i, but now it is desired to express them in terms of their direct and quadrature positive- and negative-sequence components. The direct component, i_d, of the positive-sequence current for a three-phase machine is

$$i_d=\frac{2}{3}[i_a\cos\theta+i_b\cos(\theta-120)+i_c\cos(\theta+120)] \quad (16)$$

Considering only the direct positive-sequence components of the single-phase currents

$$i_{d1}=\frac{2}{3}\frac{i}{\sqrt{3}}[\cos(t-30)\cos\theta+\cos(t-150)\cos(\theta-120)+\cos(t+90)\cos(\theta+120)]$$

$$=\frac{i}{\sqrt{3}}\cos(\theta_0+30) \quad (17)$$

Also, for the quadrature positive-sequence components of current

$$i_{q1}=-\frac{i}{\sqrt{3}}\sin(\theta_0+30) \quad (18)$$

The negative-sequence components are

$$i_{d2}=\frac{i}{\sqrt{3}}\cos(\theta_0-30) \quad (19)$$

and

$$i_{q2}=\frac{-i}{\sqrt{3}}\sin(\theta_0-30) \quad (20)$$

Substituting these relations for the current components in the line-to-line voltage equation, there is obtained

$$e_a-e_b=\sqrt{3}\Big[-e_d\sin(\theta+30)-e_q\cos(\theta+30)+i_{d1}(x_d+x_s)\times\sin(\theta+30)+i_{q1}(x_q+x_s)\cos(\theta+30)+\sqrt{3}i\left(\frac{x_d''-x_q''}{2}\right)\sin(3t+2\theta_0+60)-2i_{d1}r\cos(\theta+30)+2i_{q1}r\sin(\theta+30)\Big]$$

$$=\sqrt{3}e\cos(t+\phi) \quad (21)$$

where ϕ is the power-factor angle of the machine. Similar equations for (e_b-e_c) can be written by inspection.

Table I

Power Angle	Power Factor	Line Current	Phase
24.0	0.8 lagging	1.0	3
35.0	0.824 lagging	1.68	1
19.0	1.0	1.0	3
26.0	1	1.73	1
15.5	0.8 leading	1.0	3
20.4	0.868 leading	1.6	1

Appendix II. Starting Performance From Equivalent Circuits

The solution of the equivalent circuits for for the direct and quadrature axes of the single-phase machine give impedances of the form

$$Z_D=Z_{AD}+2(r_1+jx_1)$$

and (22)

$$Z_Q=Z_{AQ}+2(r_1+jx_1)$$

in which Z_{AD} and Z_{AQ} both contain terms for the two series rotor circuits. From Figure 5,

$$Z_D=2(r_1+jx_1)+\frac{jx_{ad}\left(\frac{r_{rd}}{s}+jx_{rd}\right)}{j(x_{ad}+x_{rd})+\frac{r_{rd}}{s}}+\frac{jx_{ad}\left(\frac{r_{rd}}{2-s}+jx_{rd}\right)}{j(x_{ad}+x_{rd})+\frac{r_{rd}}{2-s}} \quad (23)$$

$$Z_Q=2(r_1+jx_1)+\frac{jx_{aq}\left(\frac{r_{rq}}{s}+jx_{rq}\right)}{j(x_{aq}+x_{rq})+\frac{r_{rq}}{s}}+\frac{jx_{aq}\left(\frac{r_{rq}}{2-s}+jx_{rq}\right)}{i(x_{aq}+x_{rq})+\frac{r_{rq}}{2-s}}$$

The starting current is given very closely by the expression

$$i=\frac{2}{Z_D+Z_Q}\sqrt{3}e \quad (24)$$

where $\sqrt{3}e$ is the line-to-line voltage.

The rotor input is the real part of $i/\sqrt{3}$ less the stator loss. The net developed torque is the difference between the rotor input from the forward-rotating field and that from the backward-rotating field, and is

$$T=\text{real part of}\left(\frac{i}{\sqrt{3}}\right)^2\left[s\left(\frac{Z_{AD}+Z_{AQ}}{2}\right)-(2-s)\left(\frac{Z_{AD}+Z_{AQ}}{2}\right)\right] \quad (25)$$

where $(i/\sqrt{3})^2$ is the square of the *magnitude* of $i/\sqrt{3}$.

In Figure 5 the real part of $s(Z_{AD}+Z_{AQ})/2$ is

$$\frac{1}{2}\frac{\frac{r_{rd}}{s}x_{ad}^2}{(x_{ad}x_1+x_dx_{rd})^2+x_d^2\left(\frac{r_{rd}}{s}\right)^2}+\frac{1}{2}\frac{\frac{r_{rq}}{s}x_{aq}^2}{(x_{aq}x_1+x\,x_{rq})^2+x_q^2\left(\frac{r_{rq}}{s}\right)^2} \quad (26)$$

and the real part of $(2-s)(Z_{AD}+Z_{AQ})/2$ is

$$\frac{1}{2}\frac{\frac{r_{rd}x_{ad}^2}{2-s}}{(x_{ad}x_1+x_dx_{rd})^2+x_d^2\left(\frac{r_{rd}}{2-s}\right)^2}+\frac{1}{2}\frac{\frac{r_{rq}x_{aq}^2}{2-s}}{(x_{aq}x_1+x_qx_{rq})^2+x_q^2\left(\frac{r_{rq}}{2-s}\right)^2} \quad (27)$$

Performance of the Single-Phase Synchronous Machine

B. L. ROBERTSON
FELLOW AIEE

T. A. ROGERS
MEMBER AIEE

THE THEORY of operation of the single-phase synchronous machine is given by Terry and Robertson.[1] Because of its most usual manner of construction, the single-phase machine is treated as a 3-phase machine with direct and quadrature axes of symmetry and with one phase winding left idle. Of particular interest to that paper is the general analysis of the 3-phase machine as a single-phase motor or generator under steady-state operation, and the development of the expression for the line-to-line voltage with the modification of the component impedance drops as they appear normally in the treatment for the 3-phase machine.

This paper presents test data on the steady-state performance of that type of single-phase synchronous machine under both generator and motor action and for different values of power factor. They are given to substantiate the theoretical development, and in so doing show an extremely close comparison between calculation and test for complete load runs rather than for particularly chosen points. To the authors' knowledge such test data have not been presented previously. In addition, the paper shows that the harmonics in the single-phase machine practically may be neglected in the steady-state performance as given by the voltage vector diagram.

Experimental Results

Test results of torque angle and excitation under steady-state single-phase operation, and the direct comparison with calculations, for a series of load runs taken on a synchronous machine are given in Table I. The machine is a salient-pole synchronous motor with a 3-phase rating of 40-horsepower 440-volts 44.5-amperes 1,200 revolutions per minute 60-cycles. Impedance constants for the machine,[2] obtained from test measurements, are

$x_d = 1.04,\ x_q = 0.565,\ x_2 = 0.211$

and

$r_a = 0.093$, all in 3-phase per-unit terms.

The magnetization curve for the machine starts to depart from the air-gap line at about 180 volts, and at normal voltage the machine has a very high degree of saturation. Practically, to exclude attendant effects of saturation, the load runs were taken at approximately half voltage.

As observed from the data, the agreement between calculation and test is very good, particularly so for the machine operating as a motor at unity power factor and at 0.8 power factor lagging. The greatest difference shown in the table is less than five per cent and is for the machine under generator action at unity power factor. Making corrections for saturation, however, any discrepancies between calculation and test are removed and the agreement becomes practically exact.

The Vector Diagram

The vector diagram, which portrays the steady-state performance of the machine, and which in itself is the graphical solution, corresponds to the equation developed by Terry and Robertson[1] for the voltage between terminals a and b of a 3-phase machine carrying a single-phase load. Revising their equation slightly to show excitation only in the direct axis, neglecting the third-harmonic component of voltage, and expressing all voltage elements as components of the terminal voltage, we have

$$\begin{aligned} e_a - e_b = \sqrt{3}[&e_d \sin(\theta+30) - \\ &i_d(x_d+x_2)\sin(\theta+30) - \\ &i_q(x_q+x_2)\cos(\theta+30) + \\ &2i_d r\cos(\theta+30) - 2i_q r\sin(\theta+30)] \\ &= \sqrt{3}e_t\cos(t+\phi) \quad (1) \end{aligned}$$

in which

e_d = direct-axis excitation voltage per phase
e_t = terminal voltage per phase
i_d and i_q = direct- and quadrature-axis components of the positive-sequence line current i (i is 57.7 per cent of actual line current)
x_d and x_q = 3-phase direct- and quadrature-axis synchronous reactances
x_2 = negative-sequence reactance
r = armature resistance per phase
θ = angle between direct axis and axis of phase
ϕ = power factor angle

In complex notation, and for the single-phase motor with lagging power factor, equation (1) becomes

$$e_t = e_d + i_d(x_d+x_2) + ji_q(x_q+x_2) + 2i_q r - 2ji_d r \quad (2)$$

The excitation voltage, e_d, is taken as the reference vector, whence

$$i = i_q - ji_d \quad (3)$$

Because terminal conditions are given practically by the line voltage, the line current, and the power factor, it is necessary to start from these data and to locate the direct axis from them.[3] Excitation, torque angle, and the current components then are shown explicitly.

Method of Calculation

The method of calculation of the quantities given in Table I may be understood through the aid of Figure 1 which shows the voltage vector diagram for the single-phase machine. To illustrate the proce-

Paper 48-30, recommended by the AIEE rotating machinery committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26-30, 1948. Manuscript submitted October 18, 1947; made available for printing December 15, 1947.

B. L. ROBERTSON is professor of electrical engineering, University of California, Berkeley, Calif., and T. A. ROGERS is associate professor in the department of engineering, University of California, Los Angeles, Calif.

dure one set of calculations is outlined, that for the machine under motor action at 0.79 power factor lagging and with 30 amperes line current. Figure 1 was drawn for this specific case.

The terminal voltage of 0.533 (all quantities are expressed in per-unit terms) is laid off as the reference vector. The line current of 30 amperes, divided by the root of three and expressed as the decimal fraction 0.389 of normal current, is drawn from the origin at the proper power-factor angle. Next is laid off the resistance drop of 0.072, followed by the vector

$$i(x_a+x_2)=0.302$$

which locates the direct axis. The torque angle is immediately read as 33.7 degrees, comparing with 33.5 degrees as found by test. Since both components of current meet the same resistance it is not necessary to know components of the total ir drop.

With the direct axis located, the positive-sequence component of the line current is

$$i=0.388-j0.027$$

and the corresponding reactance drops are 0.301 and -0.034 per unit. The armature current is magnetizing, as always is the case under motor operation when the torque angle leads the power-factor angle. The reactance drops shown in Figure 1 determine the length of the excitation voltage, e_d, which also can be obtained from the normal projection of the tip of the vector

$$i(x_d+x_2)$$

upon the direct axis. Knowing that rated voltage, when carried to the air-gap line, requires 3.6 amperes field current, the excitation voltage of 0.34 calls for 1.23 amperes. This compares quite well with 1.25 amperes field current read during tests.

Figure 1 (above). Vector diagram for the salient-pole single-phase synchronous machine

Figure 2 (right). Wave shapes of line voltage, field current, and armature current of a single-phase machine

(a). Machine connected to an infinite bus 200-volts 39.6-amperes 7.76-kw 0.98 power factor

(b). Machine supplying a resistance load 200-volts 38.4-amperes 7.72-kw

(c). Machine supplying a resistance-capacity load. 200-volts 43.2-amperes 7.76-kw 0.89 power factor

Although armature resistance usually is neglected in synchronous machine studies, there are, nevertheless, many instances in which it has a pronounced effect and should be taken into account. This is particularly true for small machines. The effective armature resistance of the machine used in these tests is 0.054 per phase corresponding to rated line current. Because twice this phase resistance enters calculations, the resistance drop at normal current is 10.8 per cent of rated voltage and therefore is appreciable in magnitude. To neglect it would not allow the close agreement between calculated and test results which are given in the table.

Since the vector diagram does not take into account the constant losses, the reference for zero torque angle was determined at that condition of loading under which there was no electrical input to the armature of the a-c machine, all power for the losses being supplied by the d-c driver.

Harmonics

In order to show the character of the voltage and current wave shapes, and the harmonic content therein, several oscillograms were taken, the tracings of three of

them given by Figure 2. The curves indicate terminal voltage, field current, and line current, respectively, from top to bottom of the prints, the lowest line in all cases being zero field current. The test data are given with each tracing.

Figure 2*a* was obtained under pumpback operation with the machine connected through transformers to the supply of the local power company. All harmonic voltages become short-circuited at the bus, with the result that the terminal voltage is fundamental only. The current wave, however, contains odd harmonics of which the third is 21 per cent, and the fifth 4 per cent, of the fundamental. With the machine acting as a generator supplying a pure resistance load, the wave shapes are as given by Figure 2*b*. The third-harmonic voltage and current were approximately 13.5 per cent of their respective fundamentals, while the fifth-harmonic voltage and current were about 2.9 per cent. Figure 2*c*, for a generator load having a leading power factor of 90 per cent, shows wave shapes with practically the same harmonic content as those obtained under unity power factor operation. In only one case of the several investigated did the third harmonic in voltage or current exceed 25 per cent of the fundamental, and that condition was pure capacity loading on the generator. The Fourier analyses were carried out from enlarged prints of the oscillograms. Despite the fact that the difference between the direct and quadrature subtransient reactances is fairly great, and therefore accentuates the third harmonic, practically this magnitude is not such that it will affect appreciably the machine performance over that obtained by analysis treating with the fundamental alone. This conclusion is established by the data in the table.

Conclusions

The good agreement between calculation and test as shown here substantiates the theory of steady-state operation of the single-phase synchronous machine. Under the assumed condition of no saturation, the theory and actual performance check surprisingly well. The effect of armature resistance may not always be neglected without introducing serious error in both torque angle and excitation. Resistance was significant in the machine studied. It appears that the third-harmonic term which enters the line-to-line voltage equation for the single-phase machine has no effect upon steady-state performance and may be neglected with safety.

A Study of the 3-Phase Commutator Armature With Six Adjustable Brushes

PAUL W. FRANKLIN
ASSOCIATE AIEE

Synopsis: This paper attempts a detailed study of the characteristics of a three phase commutator armature with six adjustable brushes per pole pair. As the brushes are being shifted, the effective number of turns per phase, phase resistance, phase leakage reactance and flux shape, change considerably. These values are being derived as a function of the brush spacing angle and, with the help of the Goerges diagram, the resulting flux shapes are being determined. Furthermore, the change of leakage reactance with varying armature speed is being discussed. The principles of the derivations are general and may be applied to any similar problems.

CHANGES of the spacing angle between brushes of the same phase on a polyphase commutator machine cause a change of the number of effective turns per phase and thus a change in either speed or phase voltage. For his performance calculation, the designer has to know the following relations:

(*a*). Effective number of turns per phase versus brush spacing angle.

(*b*). Effective phase resistance versus brush spacing angle.

(*c*). Effective phase leakage reactance versus brush spacing angle.

(*d*). Resulting flux shape versus brush spacing angle.

(*e*). Change in leakage reactance versus varying armature speed.

In general, each phase brush current divides itself within the armature into two unequal components, these being determined by the resistance and reactance values of the two branches. For the case of the 3-phase machine, the component values are immaterial, since the conductor currents turn out to be straight fractions of the brush currents. This is due to the fact that the sum of the three positive brush currents is zero. For the case of a 2-phase machine with four brushes per pole pair, the conductor current is not independent of the current components and an accurate calculation becomes rather complicated.

For all further calculations the following fundamental assumptions are being made:

(*a*). The coil pitch shall be either 100 per cent or very close to it, so that the chord factor is unity. A coil pitch of less than 100 per cent causes even field harmonics which cannot be compensated and increase the leakage reactance of the windings.

(*b*). Brushes of the three phases shall be spaced symmetrically with regard to each other. A deviation from this again causes even field harmonics, which should be avoided.

(*c*). Brush currents are symmetrical.

(*d*). Saturation of the leakage path is neglected.

(*e*). Effects of the commutation cut in the conductor current are neglected.

Reference is made to the list of symbols given at the end of the paper.

Effective Turns Per Phase

Total number of turns per phase

$$W = \frac{z}{4c}\frac{2\alpha}{\pi} \tag{1}$$

Distribution factor for the nth harmonic

$$DF_n = \frac{\sin \alpha n}{\dfrac{N\alpha}{p\pi}\sin\left(\dfrac{p\pi n}{N}\right)} \tag{2}$$

and for a large number of slots N

$$DF_n = \frac{\sin \alpha n}{\pi n} \tag{3}$$

Figure 1. Current distribution in a single-phase armature

Paper 48-31, recommended by the AIEE rotating machinery committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted November 20, 1947; made available for printing December 12, 1947.

PAUL W. FRANKLIN is with the engineering department, Eclipse-Pioneer Instrument Corporation, Teterboro, N. J.

therefore

$$W_{eff_n} = \frac{s}{2c}\,\frac{\sin \alpha n}{\pi n} \tag{4}$$

Current Distribution

The current distribution will be derived by adding together the current distributions of three single-phase systems, spaced symmetrically in time and space for 120 degrees. Considering a single phase system (Figure 1), each brush current is split into two branch conductor currents

$$I' = k'I \tag{4a}$$

$$I'' = k''I \tag{4b}$$

with k', k'' complex constants. The resulting distribution of the slot magnetomotive force is independent of the values of k', k'' and as follows:

Arc $\overline{AD}$ and $\overline{CB}$ ..... magnetomotive force per slot $= sI\sqrt{2}$

Arc $\overline{DC}$ and $\overline{BA}$ ..... magnetomotive force per slot $= 0$

Changing now to a 3-phase system, our three brush currents are

$$I_1 = I(k' + k'') \tag{5a}$$

$$I_2 = Ia(k' + k'') \tag{5b}$$

$$I_3 = Ia^2(k' + k'') \tag{5c}$$

We have to distinguish between three cases, namely,

$\alpha = 0$–30 degrees ..... Figure 2

$\alpha = 30$–60 degrees ..... Figure 3

$\alpha = 60$–90 degrees ..... Figure 4

Figure 2. Current distribution, layer and slot magnetomotive forces in a 3-phase armature for $\alpha = 0$–30 degrees

In these figures, the current belt width, current per conductor, magnetomotive force per coil side, and resulting magnetomotive force per slot are shown and charted. The following conclusions may be drawn:

1. **For a symmetrical 3-phase system with a coil pitch of 100 per cent**

(a). **The absolute value of the current per conductor is independent of the branchc urrents and a portion of the brush current.**

(b). **The resulting magnetomotive force per slot is independent of the branch currents.**

2. For a 2-phase system or any system where the sum of the currents taken over all positive brushes is not equal to zero, we would have to state

(a). **The absolute value of the current per conductor is dependent upon the branch currents.**

(b). **The resulting magnetomotive force per slot is independent of the branch currents.**

The constant

$$m_0 = \frac{s\sqrt{2}}{c} I \tag{6}$$

is the maximum magnetomotive force per slot and used as a reference value. For our investigation of symmetrical 3-phase system, the conception of k' and k'' can be discarded from here on.

Effective Phase Resistance

We sum up the total copper losses in the armature with currents and belt widths as listed in the chart. This

copper loss is equivalent to $3I^2 R_a$ with R_a being the effective phase resistance. As a comparison value we use R_{dc} which is the resistance between two brushes spaced 180 electrical degrees apart, as used for d-c calculations. Then, for

$\alpha = 0$–30 degrees

$$R_\alpha = 4\frac{\alpha}{\pi}R_{dc} \tag{7a}$$

$\alpha = 30$–60 degrees

$$R_\alpha = 4\frac{\alpha}{\pi}R_{dc} \tag{7b}$$

$\alpha = 60$–90 degrees

$$R_\alpha = \frac{4}{3}\times R_{dc} \tag{7c}$$

This relation is plotted in Figure 5.

The Goerges Diagram and the Shape of the Air Gap Flux

The Goerges diagram, lately reintroduced by Liwschitz in one of his papers dealing with the differential leakage, is an extremely useful tool for the determination of the flux shape.

Figure 3. Current distribution, layer and slot magnetomotive forces in a 3-phase armature for $\alpha = 30$–60 degrees

If we represent each resulting slot magnetomotive force by its vector and, traveling around the armature periphery, add up all magnetomotive force vectors, we obtain a polygon which normally closes after each pole pair. The end points of these slot magnetomotive force vectors correspond to a tooth along the armature circumference, whereas the centers of these vectors correspond to the centers of slot openings. We draw a time reference line through the center of the polygon, which rotates in synchronism. It can be proved that the vertical projections from the polygon to this reference line are proportional to the resulting air gap magnetomotive force at the corresponding armature point at the time instant determined by the position of the reference line. Neglecting saturation in the iron, or estimating it, the air gap density now can be calculated and the flux shape determined.

The more this polygon approaches a circle, the more the flux shape will approach a sine curve, the less flux pulsations will occur, the less higher harmonics exist, and the smaller the differential leakage will be. It also may be seen that if the polygon is not symmetrical to any reference line, second harmonics with all their disadvantages will appear in the flux shape.

We will use the Goerges diagram for two purposes, first, to determine the flux shape, secondly, for the calculation of the belt leakage. To simplify our equations,

we assume that we have enough slots in the armature to neglect the slot steps in the flux picture, that is, we consider the case of $N \rightarrow$ infinite, with the current belt width held constant. Using the results from the charts in Figures 2–4, the diagrams are shown in Figures 6–8 as well as the flux shapes for several positions of the time reference line. The construction is indicated by the line marked v. The corners of the polygons correspond to the armature points as marked in Figures 2–4.

It is interesting to note that for $\alpha = 0$–30 degrees, several slots do not carry any current. Therefore, in the corresponding Goerges polygon, these slots merge into one polygon corner as shown in Figure 6. They cause horizontal lines in the flux picture.

Leakage Reactance Versus Varying Armature Speed

It will be necessary to analyze the components of the armature leakage reactance before deriving the necessary formulas.

The armature is fed with a current of brush frequency f_B. The current in each conductor varies with the same frequency, that is, with the exception of the commutation cut, the time differential quotient of the conductor current will be proportional to that one of the brush current.

Figure 4. Current distribution, layer and slot magnetomotive forces in a 3-phase armature for $\alpha = 60$–90 degrees

Figure 5. Effective phase resistance versus brush shifting angle

Each armature phase winding is now subjected to three different types of fluxes:

(*a*). The main (exciting) flux, crossing the air gap and interlinked with other windings in the machine.

(*b*). The leakage flux ϕ_0, caused by and interlinked only with this particular winding.

(*c*). The leakage flux ϕ_{00}, caused by and interlinked with all phase windings of the armature, but not interlinked with any other winding of the machine.

Flux (*a*) is disregarded as being immaterial to this particular consideration.

The fluxes ϕ_0 and ϕ_{00} are (neglecting leakage path saturation) proportional to the armature current and will be replaced later on by corresponding reactances X_0 and X_{00}.

Due to the commutator, the armature

Zone	No. of Slots	Upper Layer Current of Phase 1	Upper Layer Current of Phase 2	Upper Layer Current of Phase 3	Total Current in Upper Layer	Total Mmf in Upper Layer	Lower Layer Current of Phase 1	Lower Layer Current of Phase 2	Lower Layer Current of Phase 3	Total Current in Upper Layer	Total Mmf in Lower Layer	Total Mmf per Slot

Figure 6. Goerges polygon and flux shapes for $\alpha = 0$–30 degrees

Figure 8. Goerges polygon and flux shape for $\alpha = 60$–90 degrees

can be considered as a normal 3-phase winding, stationary in space, with the winding axes being determined by the brush position. The flux ϕ_0 interlinked with one strand only, pulsates in space with brush frequency. The flux ϕ_{00}, which is actually the sum of three pulsating phase fluxes, rotates in space with brush frequency.

We imagine our leakage voltage to be generated by the armature conductors, rotating in space with speed frequency f_B, cutting the lines of the fluxes ϕ_0 and ϕ_{00}. The pulsating flux ϕ_0 is replaced by two rotating fluxes $\phi_0/2$, rotating in space with $+f_B$ and $-f_B$.

The amplitude of the induced leakage voltage is

$$E_L = K\left(\frac{\phi_0}{2}(f_B - f_R) + \frac{\phi_0}{2}(f_B + f_R) + \phi_{00}(f_B - f_R)\right) \quad (8a)$$

$$= K(\phi_0 f_B + \phi_{00}(f_B - f_R)) \quad (8b)$$

and substituting corresponding leakage reactances X_0 and X_{00}, both calculated at line frequency, we obtain

$$E_L = I\left(X_0\frac{f_B}{f_L} + X_{00}\left(\frac{f_B - f_R}{f_L}\right)\right) = IX_L \text{ per phase} \quad (8c)$$

The frequency of this leakage voltage, as appearing at the brushes, is always brush frequency.

Two practical cases are being considered.

(*a*). Brush frequency = line frequency (series and shunt motor)

$$f_B = f_L$$
$$f_R = (1 - S)f_L$$
$$X_L = X_0 + SX_{00} \quad (9)$$

(*b*). Brush frequency = slip frequency (Schrage motor)

$$f_B = Sf_L$$
$$f_R = -(1 - S)f_L$$

since the armature rotates opposite to the phase rotation,

$$X_L = SX_0 + X_{00} \quad (10)$$

Our conclusion is

(*a*). The total armature leakage reactance consists of two terms, one which remains constant and the other one being proportional to armature slip.

(*b*). The total armature leakage flux consists of two terms, one caused by and interlinked with one phase only, the other caused by and interlinked with all armature phases.

(*c*). The single interlinked leakage flux consists of a small part of the slot flux and a small part of the winding extension leakage flux.

(*d*). The double interlinked flux consists of most of the slot leakage flux, all of the differential or zig-zag or belt flux, all of the banding flux and most of the winding extension flux.

(*e*). The double interlinked leakage flux is usually much larger than the single interlinked leakage flux.

Figure 7. Goerges polygon and flux shapes for $\alpha = 30$–60 degrees

Differential Leakage Reactance

The derivation of the differential leakage will be the same as the method published by Liwschitz and his predecessors, except that the principal formula will be derived by means of the magnetic energy stored in the airgap.

Assuming a winding with M phases with the current I and infinite permeability in the iron, the magnetic energy stored in the airgap is

$$E_G = \frac{M}{4\pi f}X_G I^2 \quad (11)$$

The energy accounted for by the first harmonic is

$$E_1 = \frac{M}{4\pi f}X_m I^2 \quad (12)$$

with X_m the usual magnetizing reactance.

Inasmuch as the difference $E_G - E_1$ has to be accounted for in the total reactive energy balance, a virtual reactance, the differential reactance, is being introduced to

$$X_d = X_G - X_m \quad (13)$$

We can calculate the total magnetic energy in the air gap to

$$E_G = \frac{1}{2}\int^{G} h \cdot b \cdot dq \quad (14)$$

the integral being taken over the whole air gap and with

$dq = l_e \delta h_e dx$ volume element (14a)

$b = \Pi_0 h$ in air (14b)

$$\Pi_0 = \frac{4\Pi}{10}10^{-8} \quad (14c)$$

Introducing v = magnetomotive force in ampere turns at point x in the air gap to

$$v = \delta k_c h \quad (15)$$

4–5	$u\frac{N}{p}\left(\frac{1}{2}-\frac{\alpha}{\pi}\right)$	$\frac{I}{c}$	$-a\frac{I}{c}$	$C\frac{p}{a}u\frac{N}{p}\left(\frac{1}{2}-\frac{\alpha}{\pi}\right)\left\{f_a(\lambda_{11}+\lambda_{21})\left(\frac{I}{c}\right)+2f_b\lambda_{12}\left(-a\frac{I}{c}\right)\right\}$
5–6	$u\frac{N}{p}\left(\frac{\alpha}{\pi}-\frac{1}{3}\right)$	$-a\frac{I}{c}$	$-a\frac{I}{c}$	$C\frac{p}{a}u\frac{N}{p}\left(\frac{\alpha}{\pi}-\frac{1}{3}\right)\left\{f_a(\lambda_{11}+\lambda_{21})\left(-a\frac{I}{c}\right)+2f_b\lambda_{12}\left(-a\frac{I}{c}\right)\right\}$

Total reactance voltage between brushes of the same phase

$$e=\frac{\pi^2}{5}\frac{2^2}{Nc^2}I\left\{f_a(\lambda_{11}+\lambda_{21})\frac{1}{3}+2f_b\lambda_{12}\times\left(\frac{\alpha}{\pi}-\frac{1}{6}\right)\right\}10^{-8}\cdot I \text{ volts}$$

we see that v may be taken directly from the Goerges diagram as the vertical projection on the time reference line.

After some straightforward calculations, we obtain

$$E_G=\frac{pl_1\Pi_0\tau}{\delta k_c N}\sum v^2 \tag{16}$$

$$X_G=\frac{4\pi f p l_1\Pi_0\tau}{\delta k_c N M_1^2}\sum v^2 \tag{17}$$

The summation $\sum v^2$ requires the sum of the square of all projections in the Goerges diagram over all teeth of the armature.

Since

$$X_m=\frac{MW^2_{eff}l_1\Pi_0 A f\tau}{\delta k_c p\pi} \tag{18}$$

$$X_d=\sigma X_m \tag{19}$$

with

$$\sigma=\left(\frac{p\pi}{MW_{eff}I}\right)\sum\left(\frac{v^2}{N}\right)-1 \tag{20}$$

Theoretically we should develop now a formula including all values of N and α. This leads to an extremely complicated procedure and we, therefore, resort to the well known approximation to split the differential leakage into

(*a*). Tooth-top leakage (added to slot leakage).

(*b*). Belt leakage (differential leakage for $N \to$ infinite).

The term $\sum v^2$ is nothing else but the axial moment of inertia of the Goerges polygon. For our assumption of $N \to$ infinite, it changes to

$$\sum v^2=\sum\int_{N1}^{N2} v^2(N)dN \tag{21}$$

the integral being taken over the boundary lines of the polygon. Since the polygon is symmetrical with regard to the center (no second harmonics), the axial moment, according to Richter,[4] is independent of the instantaneous position of the reference line.

The calculation of $\sum v^2$ is tedious, though straightforward and will not be reproduced here. Reference is made again to Richter[4] and Liwschitz.[3]

We finally obtain

$\alpha = 0$–30 degrees

$$\sigma=\frac{\pi^4}{9}\frac{\left(\frac{\alpha}{\pi}\right)^2}{\sin^2\alpha}\left(1-\frac{\alpha}{\pi}\right)-1 \tag{22}$$

which degenerates for $\alpha \to 0$ to

$$\frac{\pi^3}{9}-1 \tag{22a}$$

the same value as the belt leakage factor for one slot per pole and phase.

$\alpha = 30$–60 degrees

$$\sigma=\frac{8\pi^4}{9\sin^2\alpha}K-1 \tag{23}$$

$$K=-\frac{k^3}{4}+\frac{3}{16}k^2-\frac{k}{96}+\frac{1}{1{,}728} \text{ with } k=\frac{\alpha}{\pi} \tag{23a}$$

$\alpha = 60$–90 degrees

$$\sigma=\frac{8\pi^4}{9\sin^2\alpha}K-1 \tag{24}$$

$$K=-\frac{k^3}{8}+\frac{k^2}{16}+\frac{k}{32}-\frac{7}{1{,}728} \tag{24a}$$

The values for σ are shown in Table I.

This belt leakage X_d forms part of the double interlinked leakage reactance $X_{\sigma\sigma}$. Therefore, if the brush frequency is

$f_B = f_{line}$, X_d is proportional to slip S

$f_B = f_{slip}$, X_d is proportional to line frequency

Inasmuch as the winding in the opposite part of the machine is not a squirrel cage winding, any damping effects may be safely neglected.

Slot and Tooth-Top Leakage Reactance

We will proceed in the following manner: first, we calculate the leakage voltage per coil side, then per coil, then per commutator bar, and finally we sum up all bar voltages between brushes of the same phase. Our calculation will be exact only for integer values of $\frac{N}{P}\frac{\alpha}{\pi}$ but interpolations are permissible.

A slot of the shape shown in Figure 9 is assumed. For semienclosed slots, the respective values of λ will have to be changed in accordance with well known formulas.

Reactance voltage in upper coil side of coil considered

$$e_u=2\pi(f_a L_{11}i_1+f_b M_{12}i_2') \tag{25a}$$

with i_1 = current in upper coil side, i_2' = current in coil side below this particular coil side.

Reactance voltage in lower coil side of coil considered

$$e_l=2\pi(f_a L_{22}i_1+f_b M_{12}i_2'') \tag{25b}$$

Figure 9 (left). Slot

Figure 10 (right). Winding extension

with $i_2'' =$ current in coil side above this particular coil side.

For 100 per cent coil pitch, $i_2' = i_2''$. As to f_a, f_b, we will designate their values later on.

$$L_{11,22} = \frac{4\pi}{10} l \lambda_{11,22} u r^2 10^{-8} \tag{26}$$

$$M_{12} = \frac{4\pi}{10} l \lambda_{12} u r^2 10^{-8} \tag{27}$$

$$\lambda_{11} = \frac{H}{3A} + \lambda_0 \tag{28a}$$

$$\lambda_{22} = \frac{H}{3A} + \frac{G+H}{A} + \lambda_0 \tag{28d}$$

$$\lambda_{12} = \frac{H}{2A} + \lambda_0 \tag{28c}$$

$\lambda_0 =$ slot permeance on top of upper coil, including tooth-top leakage (28b)

Reactance voltage per coil

$$e_{coil} = e_u + e_l = C\{f_a(\lambda_{11} + \lambda_{22})i_1 + 2f_b\lambda_{12}i_2\} 10^{-8} \text{ volt} \tag{29}$$

$$C = \frac{8\pi^2}{10} l u r^2 10^{-8} \tag{29a}$$

The voltage per commutator bar is

$$e_{bar} = e_{coil}\frac{p}{c} \tag{30}$$

and it remains to sum up these voltages between brushes of the same phase.

Such a summation is shown as a sample for $\alpha = 60$–90 degrees in Table II. The zonal points referred to correspond to the arrangement shown in Figure 4. Keeping in mind that

$$\frac{z}{4c} W = \frac{Nur}{2c} = \frac{sN}{4c} \tag{31}$$

we obtain as the result of the sample calculation and similar calculations

$\alpha = 0$–30 degrees

$$X_{slot} = \frac{\pi^2}{5}\frac{z^2}{Nc^2} l \left\{ f_a(\lambda_{11} + \lambda_{22})\frac{\alpha}{\pi} \right\} 10^{-8} \tag{32a}$$

$\alpha = 30$–60 degrees

$$X_{slot} = \frac{\pi^2}{5}\frac{z^2}{Nc^2} l \left\{ f_a(\lambda_{11} + \lambda_{22})\frac{\alpha}{\pi} + 2\lambda_{12} f_b\left(\frac{\alpha}{\pi} - \frac{1}{6}\right) \right\} 10^{-8} \tag{32b}$$

$\alpha = 60$–90 degrees

$$X_{slot} = \frac{\pi^2}{5}\frac{z^2}{Nc^2} l \left\{ f_a(\lambda_{11} + \lambda_{22})\frac{1}{3} + 2\lambda_{12} f_b\left(\frac{\alpha}{\pi} - \frac{1}{6}\right) \right\} 10^{-8} \tag{32c}$$

with l measured in centimeters.

The first term within the bracket corresponds to the leakage flux interlinked with one phase only; the second to the double interlinked flux. Consequently we can substitute for

$$f_B = f_L \quad f_a = f_L \quad f_b = Sf_L$$
$$f_B = Sf_L \quad f_a = Sf_L \quad f_b = f_L$$

End Extension Reactance

One ampere, flowing in an end extension conductor, will excite

$$\frac{4\pi}{10}(\lambda' + \lambda'')$$

magnetic flux lines per one inch length. Part of these flux lines will be interlinked with the conductor only (λ') and the rest with all other phases (λ''). The values λ' and λ'' depend very much upon the mechanical shape of the extension, steel banding and distance between primary and secondary winding. Unfortunately, these constants are not as accessible to mathematical treatment as the other leakage constants.

If we assume now that the magnetomotive force of the current belt along the extension is a sine wave (neglecting higher harmonics and thus committing an error of the magnitude of $\sqrt{\sigma}$), we may write

$$X_{ext} = 4\pi \frac{M}{2} p(f_a L' + f_b L'') \tag{33}$$

with L being the inductance correponding to λ' and λ''.

$$L = \frac{W^2_{eff}}{p^2} l_{ext} \lambda \frac{4\pi}{10} 10^{-8} \tag{33a}$$

$$X_{ext} = \frac{8\pi}{10}\frac{W^2_{eff}}{p}(f_a\lambda' + f_b\lambda'') l_{ext} M 10^{-8} \tag{34}$$

Very hesitatingly, since each designer has to derive this formula for his type of design, the author quotes

$$l_{ext}\lambda'' = 0.82\left(a + \frac{b}{2}\right) \tag{35}$$

with reference to Figure 10 and a and b measured in inches.

Corrections for banding and proximity of iron are not included in this formula.

Since the conductors of the extension are close together in most designs, λ' can be neglected and the end extension leakage flux is interlinked entirely with all phases. Hence, we can write for

$$f_B = f_{line};\ f_b = Sf_L;\ f_a = 0 \tag{36a}$$

$$f_B = Sf_{line};\ f_b = f_L;\ f_a = 0 \tag{36b}$$

It is, however, not too difficult to measure the leakage end extension flux with a probing coil and thus actual values of λ'' may be obtained.

Conclusion

In a 3-phase armature with two brushes per phase and coils with 100 per cent pitch, the current distribution in the conductors is independent of the resistance and leakage values of the individual branches, regardless of brush shift. Hence, simple effective resistance and leakage reactance formulas may be derived. The total leakage flux is split up into a single and double interlinked flux, creating two components of the leakage reactance, which vary in a different manner with regard to the speed of the armature. The derivation presented covers all resistance and leakage reactance values as a function of the brush spacing as well as the Goerges diagram and the shape of the armature flux. This method of analysis is adaptable to all resistance and reactance calculations for windings with or without commutators.

List of Symbols

$\alpha =$ brush spacing angle in electrical degrees (total electrical angle between phase brushes $= 2\alpha$)
$a =$ operator $= e^{j120°}(1 + a + a^2 = 0)$
$b =$ magnetic field density
$c =$ number of pairs of parallel branches in armature ($= 1$ for single wave winding)
$\delta =$ mechanical air gap in centimeters
$DF_N =$ distribution factor for nth harmonic
$e_u, e_l =$ reactance voltage in upper, lower coil side
$E_G =$ magnetic energy in gap
$E_1 =$ magnetic energy of first harmonic flux
$f_B =$ brush frequency
$f_R =$ rotational frequency
$f_L =$ line frequency
$f_a f_b =$ frequencies as defined in text
$\phi_0, \phi_{00} =$ leakage fluxes
$h =$ magnetic field strength
$I =$ brush current
$I', I'' =$ branch currents
$i_1, i_2', i_2'' =$ currents in coil sides
$k', k'' =$ complex factors (absolute value smaller than unity)
$k_c =$ Carter factor
$k = \frac{\alpha}{\pi}$
$K =$ constant
$l =$ actual core length in centimeters
$l_l =$ effective core length in centimeters
$l_{ext} =$ average extension length per conductor per side
$L_{11}, L_{11}, L_{22}, L_{12} =$ inductances
$\lambda_{11}, \lambda_{22}, \lambda_{12}, \lambda_0 =$ slot leakage permeance
$\lambda', \lambda'' =$ coil extension leakage permeance
$m_0 =$ maximum magnetomotive force per slot in ampere turns
$M =$ number of phases
$M_{12} =$ mutual inductance
$n =$ integer of harmonic
$N =$ number of slots
$p =$ number of pole pairs

r = turns per coil side

R_a = effective phase resistance

R_{dc} = diameter brush resistance (d-c resistance)

s = total conductors per slot

S = slip

σ = belt leakage factor

τ = pole pitch in centimeters

u = coil sides per slot layer

v = magnetomotive force in air gap in ampere turns

W = turns per phase

W_{effn} = effective turns per phase for nth harmonic

x = free co-ordinate along armature periphery

X_{1s}, X_{2s} = leakage reactance

X_G = total reactance of air gap

X_L = total leakage reactance

X_m = magnetizing reactance for 1st harmonic

X_d = differential reactance

z = total conductors in armature $= sN = 2urN$

Quadrature Operation of Filamentary Thermionic Gas Tubes

V. L. HOLDAWAY
ASSOCIATE AIEE

Synopsis: Filamentary thermionic gas tubes, when operating with the anode and filament voltage inphase, exhibit a marked temperature gradient along the filament. When the magnitude of the anode and filament currents are of comparable value, the resulting nonuniformity in filament temperature may be sufficient to cause short tube life and unreliable operation. This condition is not corrected appreciably by any special arrangement of anode current return connection to the filament circuit.

By operating the tube with the anode and filament voltages in quadrature,[1] approximately double the value of current permissible under the inphase operating condition may be conducted before the same temperature difference results.

General

THE CATHODE in a thermionic gas tube is capable of supplying an emission current of several amperes per square centimeter. When the tube is of the oxide-coated filamentary type, the maximum rated peak anode current may be larger than the nominal filament current, and the rated average anode current may be a substantial fraction of the nominal filament current. This is true especially of the low-voltage rectifier tubes and thyratrons.

In the most common use of these tubes in rectifier or inverter circuits, the filament is supplied normally from an alternating voltage and the anode current is caused to flow for some fraction of the cycle of the fundamental frequency. Considering the single-phase circuit with the filament and anode voltage inphase, the anode current will be conducted during a portion of the cycle in which the filament current flows in one direction.

The current in the filament from point-to-point will not be equal due to the emission current leaving the filament and unequal heating will result. When the value of anode current returned to the filament is comparable in value to the filament current an appreciable filament temperature change is produced.

Two other effects which cause a filament temperature change but which are secondary to the ohmic loss are electron evaporation and positive ion bombardment.[2,3] The cooling effect resulting from electron evaporation and the heating effect resulting from positive ions returning to the filament tend to cancel. In the mercury vapor and low pressure gas-filled rectifiers and thyratons considered in this paper, the net temperature change from these two factors was found to be small. This is not true of all types of thermionic gas tubes, however, as for example in the gas-filled tungsten-filament tungar type rectifier. In this type of tube the high emission current density, high-gas pressure and low tube voltage drop produces an appreciable net electron cooling effect. A filament temperature drop of over 100 degrees centigrade may be observed at full load.

In the design of the emitter for a thermionic gas tube, the optimum filament temperature has been determined by life tests for the various tube types and uses. For any particular type and use, plus or minus 25 degrees centigrade would be a representative allowable variation about the design center.

Paper 48-32, recommended by the AIEE electronics committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted November 13, 1947; made available for printing December 10, 1947.

V. L. HOLDAWAY is a member of the technical staff of Bell Telephone Laboratories Incorporated, New York, N. Y.

To allow this total variation in temperature to appear along the filament in an individual tube, however, would be very undesirable. Nonuniform temperatures and the resulting nonuniform emission has several deleterious effects:

1. Active material is lost more rapidly from the hot area as a result of the increased rate of evaporation.

2. Hot-spots are likely to form which may result in destructive forward arcing.[4]

3. The rapid rate of accumulation of active materials on the anode increases the likelihood of arc-back.[5]

4. The cold area, as well as not supplying the proper share of emission current, is more likely to accept deposits of sputtered material. The resulting overlay of contaminants greatly reduces the emission capabilities of that area. All of these contribute to unreliable operation and shorter tube life.

Determination of Temperature Difference

To evaluate the filament temperature change resulting from the conduction of anode current, tests were made under four circuits conditions as shown in Figures 1*a*, 2*a*, 3*a*, and 4*a*. A half-sine wave of anode current was conducted in the tests as the wave shapes in actual rectifiers and inverters differ so greatly it is not possible to select any one shape as typical. The filament temperature was measured by means of an optical pyrometer having a sensitivity of plus or minus five degrees centigrade. The filament was viewed during the interval when the anode current was zero by interposing a synchronous motor-driven rotary shutter between the observer and the pyrometer.

Tests were made on a laboratory tube model having a 2.5-volt 3.0-ampere folded mesh filament, and on a special Western Electric *267B* tube provided with observation holes in the filament heat casement. The latter tube is a medium power half-wave mercury vapor rectifier. It employs a shielded oxide-coated folded nickel mesh filament. The filament is designed to operate at 5.0 volts and the nominal filament current is 6.75 amperes. The peak inverse

anode voltage rating is 7.5 kv. The anode current rating for inphase operation is 1.0-ampere average and 4.0-amperes peak, and for quadrature operation 2.0-amperes average and 8.0-amperes peak.

The results of the filament temperature tests on the laboratory model and the *267B* type were similar and only those on the latter type are presented.

Inphase Operation

In the single-phase circuit the tube conducts for approximately one-half cycle. When the filament and anode voltages are inphase, the filament current flows in one direction only during the anode conduction period. Under these conditions it will be noted, by referring to Figure 1*a*, that the anode current passing through the filament circuit adds to the filament current at one end of the filament and substracts from the filament current at the other. The I^2R power input is hence unequal near the two filament ends, causing increased heating of one and decreased heating of the other. The resulting temperature difference causes the hotter end to supply a greater share of the emission current which further accentuates the temperature difference.

The d-c resistance of the low-voltage winding of the filament transformer is, in general, less than 10 per cent of the filament resistance. This results in a reasonably equal division of the anode current returned to the filament ends, regardless of the point at which the anode circuit returns to the filament transformer. There is sufficient inequality of current division, however, to produce a noticeable change in the temperature of the filament midpoint and a smaller change in the temperature of the filament ends, as shown by the data.

The data are presented in graph form. Filament brightness temperatures in degrees centigrade are plotted as ordinate against the ratio of anode current to filament current, expressed as peak values, as abscissce. An insert *a* of the circuit, and *b* of the representative current waves, is included in each figure.

Figure 1 shows the resulting filament temperatures when the anode current return is connected to one end of the filament. The transformer polarity is such that the filament and anode currents are aiding in the number 1 end of the filament. At some point along the filament the anode current will be zero. This point will lie between the midpoint and the number one end because of the transformer resistance. Between this point and the number one end the two currents are aiding and cause increased heating, while between this point and the number two end the currents are in opposition and cause decreased heating. As the resistance per inch of filament is considerably higher in the hot end, and as a major share of the emission current is supplied by this end, the filament mid-

Figure 4. Quadrature operation

Anode current return connection to filament end. Phase angle = 90 degrees. Western Electric 267B tube

point and the number 2 end operate at greatly reduced temperatures. A temperature difference of 50 degrees centigrade is reached between the filament ends when the peak anode current is approximately 30 per cent of the peak filament current. This circuit is the least desirable as three-fourths of the filament operates below normal temperature.

The effect of reversing the polarity of the filament transformer is shown in Figure 2. In this case the point along the filament at which the anode current is zero will be nearer the cool end of the filament. The hot end operates at a temperature slightly higher than in the preceding case but the temperature gradient is more uniform and the midpoint operates at a temperature slightly above normal. The ratio of peak anode current to peak filament current is approximately 40 per cent when an end temperature difference of 50 degrees is reached.

Figure 3 gives the performance when the anode current return is made to the midpoint of the filament transformer. The temperature conditions are slightly improved over the preceding two conditions and a peak anode current of approximately 50 per cent of the peak filament current may be conducted before the arbitrary 50 degree centigrade difference is attained.

It may be pointed out that an anode circuit return made directly to the midpoint of the filament would further improve the conditions. The maximum heating effect would occur directly to one side of the return point and the maximum cooling effect directly to the other side. The two opposing effects would tend to cancel each other by radiation and heat conduction along the filament.

Quadrature Operation

Filament temperatures resulting under quadrature operating conditions are shown in Figure 4. The filament voltage is taken from line to line of the three-phase power supply and the anode voltage taken from line to neutral as indicated in Figure 4*a*. This provides a 90 electrical degree phase angle between the filament and anode voltages. The anode circuit return is made to one side of the filament as only a small gain in filament temperature uniformity is obtained by a transformer mid-point return.

When the tube is operated with the filament and anode voltages in quadrature, the filament current flows in one direction for one-half of the anode conduction period and in the opposite direction for the other half, Figure 4*b*. This results in a symmetrical heating and cooling effect in the two filament ends. The net result is a slight increase in the temperature of the filament midpoint and a larger but equal increase in temperature of the

filament ends. It is seen that the magnitude of the peak anode current may approach that of the peak filament current before an end temperature rise of 25 degrees above normal is reached. If the no-load filament voltage is adjusted to give a filament temperature 25 degrees below normal, a peak anode current approximately 140 per cent of the peak filament current may be tolerated before a 50 degrees end temperature rise is produced.

Life Tests

Adequate life tests demonstrating the merits of quadrature operation are not available. Tests attempting to show differences of this kind conclusively involve large numbers of tubes and are time consuming and costly. There are at hand, however, some life data showing related effects.

Tests conducted on the Western Electric *301A* tube, a small full-wave mercury-vapor rectifier, indicate the adverse effect of high current operation. This tube employs a 5-volt 3-ampere filament divided into two separate sections, each with its enclosing anode. It is rated at 0.5-ampere average anode current per section and 2.0-amperes peak anode current.

The tubes were operated under an overload condition of 1.75-amperes d-c output in a full-wave circuit with inphase filament excitation. This corresponds to a peak current of approximately 2.5 amperes and a ratio of 60 per cent peak anode current to peak-filament current. The temperature difference between the ends of the filament was approximately 85 degrees centigrade. The life obtained under these conditions was approximately one-third normal. While no comparative quadrature life runs were made on this tube type, the manner in which the filament failed is significant. The two filament sections are in series which results in one section operating above normal, and the other below normal temperature. In general the hot section would be the first to lose emission to the point of failure. The emission loss of the cold section, however, would be nearly as great. An examination of the filaments of the failed tubes showed that the hot section had lost emission primarily through the loss of coating material by evaporation and bombardment, and that the cold section had lost emission primarily as the result of an overlay of sputtered material. The hot section also was more subject to arcback during the test.

Life tests on the Western Electric *267B* half-wave mercury-vapor rectifier tube were not completed. This test was made in a six-tube three-phase bridge type circuit with a filtered load. Two tubes were operated under the inphase condition, and four tubes under the quadrature condition. The d-c output was 5 amperes at 9 kv with a peak anode current of 5.5 amperes which was the maximum permissible load for the equipment available. Under these conditions the temperature difference of the filament ends was approximately 50 degrees centigrade for the tubes with inphase filament excitation. The filament end temperature rise was less than 10 degrees centigrade for the tubes operating in quadrature. The test was discontinued at 11,000 hours. At this time all tubes were operating satisfactorily, but the individual tube tests indicated a somewhat greater loss of emission for the tubes in the inphase condition.

Conclusions

Inphase operation of filamentary gas-filled rectifier and thyratron tubes at high anode currents results in an undesirable temperature difference along the filament.

This condition may be improved considerably by operating the tube with the anode and filament currents in quadrature. This type of operation will allow a substantial increase in anode current before the same temperature change from the designed optimum is encountered.

The life tests on the *301A* tube previously cited indicate that a filament end temperature difference of 85 degrees centigrade results definitely in a considerable sacrifice of tube life. On the other hand, the 50 degree difference in the *267B* life test did not result in a shortening of tube life that was readily measurable. Conservative engineering practice would dictate that a reasonable margin of safety be allowed in establishing maximum permissible temperature differences or anode currents. The maximum anode current for inphase operation, therefore, may be such as to limit the filament end temperature difference to perhaps 25 to 50 degrees centigrade. Similarly, the maximum anode current for quadrature operation is found to be approximately double this value.

In many rectifier installations, such as large high-voltage rectifiers, even though the tubes are not worked to the limit of their ratings, quadrature operation is desirable. The cost of providing quadrature excitation is small and may be justified by even a small increase in life expectancy and reliability of operation.

A Method for the Measurement of the Ionization and Deionization Times of Thyratron Tubes

MILTON BIRNBAUM
NONMEMBER AIEE

IN THE DESIGN of pulse circuits employing thyratron tubes, the ionization and deionization times are important tube characteristics which determine to a considerable extent the operation and limitations of the particular circuit in which they are employed. Nevertheless, there exists little published information on these tube characteristics which could serve as a basis for circuit design. Although several studies have been undertaken to establish the mechanism of thyratron breakdown and extinction, and scientific descriptions of the processes are presented, none has set forth a method of computing these quantities which produce results in close agreement with laboratory measurements.[1–4]

In view of this situation, the measurements described in this paper were undertaken at the Naval Research Laboratory to provide data on the ionization and deionization times of several common types of thyratron tubes. At the time the author was securing this information, the emphasis was upon speed rather than completeness and, therefore, not all available tube types were included in the tests, nor were the effects of the variations of all the circuit parameters upon ionization and deionization times fully investigated.

Ionization-Time Measurements

The ionization time of a thyratron is broadly speaking, a measure of the time interval between the application of a trigger pulse and the time at which the thyratron starts conduction. By using a rectangular trigger pulse, with a rise time that is small as compared to the ionization time of the thyratron, the ionization time as a function of the amplitude of the trigger pulse is obtained. If a trigger pulse with a sloping front is employed, the attempt to plot starting time as a function of trigger amplitude encounters the following limitation. As the amplitude of the trigger pulse is increased, a point will be reached where ignition of the thyratron occurs along the sloping front of the trigger pulse, and further increases in the trigger amplitude, unless the slope of the pulse changes, need not alter the starting time. To extend the graph to regions of shorter starting times, trigger pulses with faster rise times must be employed; to explore the regions of shortest starting times, rectangular trigger pulses are required.

A circuit capable of generating rectangular pulses with rise times less than 0.01 microsecond and with amplitudes greater than 200 volts is shown in Figure 1. Upon ignition of the *2D21* thyratron, the charged delay line in its anode circuit commences to discharge through the cathode load resistor and the *2D21*. This flow of current continues for a period determined by twice the length of the delay line, since this is the time required for the step voltage of negative polarity to travel down the line, suffer a reflection without a polarity change at the open end of the line, and return to the anode. The appearance of this negative pulse at the anode pulls the anode down to a potential below the cathode potential and conduction ceases. The necessary condition for circuit operation in the manner just described is that the cathode load resistor be less than, or at most equal to, the characteristic impedance of the delay line. The resistor in the thyratron anode circuit must be so selected that the *RC* time constant (the *C* here is the line capacitance) is sufficiently short to allow the line to recharge fully at the required repetition rate and that the rate at which the line recharges is slow enough to permit the tube to deionize before the anode rises to a voltage high enough to produce reignition. The use of a low-impedance line is consistent with the rapid pulse rise time requirement since a large value of peak current is necessary to charge the stray circuit capacitances in less than 0.01 microsecond.

The following expedients were resorted to in order to produce a flat-topped pulse: use of a delay line with distributed parameters (a roll of 75-ohm coaxial cable) and a 150-ohm resistor in the grid circuit of thyratron 2. With this arrangement, the peak to peak ripple voltage along the top of the pulse rarely exceeded ten per cent of the pulse amplitude.

By variation of the anode voltage of thyratron 1, the output pulse can be

Figure 1. Circuit for ionization-time measurements

Input—A positive trigger at approximately 50-volt amplitude and of 1-microsecond duration supplied by a synchroscope

Paper 48-33, recommended by the AIEE electronics committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted August 11, 1947; made available for printing December 15, 1948.

MILTON BIRNBAUM is with the Naval Research Laboratory, Washington, D. C.

The methods described for measurement of both the ionization and deionization time characteristics of thyratrons were suggested by F. H. Wells, who supervised this work. The views presented in this paper represent those of the author and are not necessarily those of the Naval Research Laboratory.

Figure 2. Starting-time curves (2A4)

Figure 5. Starting-time curve (6D4)

Figure 3. Starting-time curves (2C4)

Figure 4. Starting-time curve (884)

Figure 7. Starting-time curves (2D21)

varied in amplitude from 250 volts to 50 volts. Below 50 volts, the pulse rise time commences to deteriorate rapidly. Therefore, to produce a satisfactory pulse less than 50 volts in amplitude, a 150-ohm potentiometer is connected in parallel with the 68-ohm resistor in the cathode of thyratron 1. The output is then taken from the potentiometer tap and may be varied by changing the position of the tap. This procedure was not employed throughout the tests since the potentiometer in the cathode of thyratron 1 resulted in an increase in the ripple voltage on the pulse top.

Figure 8. Starting-time curves (3C45)

Figure 10. Deionization-time curves; tube type 884

Figure 9. Circuit for deionization-time measurements

Input 1—Fixed positive pulse (approximately 10 microseconds wide, 50-volt amplitude)

Input 2—Delayed positive pulse (approximately 20 microseconds wide, 50-volt amplitude)

The starting-time measurements were obtained by the use of a synchroscope which supplied triggers for the pulse-generator circuit and a linear sweep with a speed of one centimeter per 0.1 microsecond. By first displaying on this sweep the leading edge of the rectangular pulse and then the leading edge of the thyratron 2 pulse, and noting the distance between the two edges, the time interval between them could be estimated with an accuracy of ±0.01 microsecond. The distance between the leading edges of the two pulses was taken as the distance between the center section of each pulse front.

An alternate method of measuring the thyratron ionization time provided an excellent verification of the results obtained by the procedure just outlined. If the inspection probe of the synchroscope is placed upon the grid of thyratron 2, the rectangular pulse is seen on the oscilloscope screen, and the instant thyratron 2 breaks into conduction is indicated by the deformation of the thyratron 1 pulse. The deformation of the thyratron 1 pulse at that instant is due to the change in grid impedance of thyratron 2 when ignition of thyratron 2 occurs. This procedure is equivalent to that of displaying the thyratron 1 and the thyratron 2 pulses simultaneously.

Table I of starting time characteristics for rectangular trigger pulses is provided as a reference guide and also as a summary of the data contained in Figures 2–8. Most of the tube types were tested at two values of anode voltage. In this respect, special attention should be given to tube type *2050*, since its variation of starting time with anode voltage (for the same grid overvoltage) is considerable.

Deionization-Time Measurements

In order to measure the deionization-time characteristics of thyratron tubes, the following procedure was adopted. The thyratron is brought into conduction and immediately after this, the anode of the thyratron is maintained at a predetermined potential below its cathode potential. At various intervals of time, the anode voltage is suddenly applied. The maximum voltage which can be

Figure 11. Deionization-time curves; tube type 2050

applied without causing reignition, is a measure of the extent to which the thyratron has deionized. In this manner, a graph showing anode reignition voltage as a function of the time after ignition may be plotted.

The circuit shown in Figure 9 was used to obtain the deionization time data. A pulse and sweep generator (Hazeltine test rack model *1021*) supplies the fixed pulse (called "fixed" since it serves as a reference time) which is applied to the grids of *6J6* amplifier stage. The outputs of triodes (1*a*) and (1*b*) serve respectively, to trigger the thyratron 6 and the one-kick multivibrator (2). From the multivibrator, the proper grid drive for the amplifier (3) is obtained. It consists of a negative pulse longer in duration than twice the deionization time of the thyratron under test (a 1,000-microsecond pulse fulfilled this requirement for all the tubes tested) and is adjustable in amplitude by means of the potentiometer in the cathode of the multivibrator (2). This pulse is amplified by the *6V6* (3), and the output (a pulse of positive polarity) is used to drive the grid of tube 5. The flow of plate current of amplifier 5 through its plate load, holds the anode of the thyratron at a potential of approximately −20 volts. The rate of rise of the multivibrator pulse is sufficiently slow to prevent this action from occurring before the thyratron (6) has been triggered.

The delay line in the anode circuit of thyratron (6) is used only to simulate the contemplated operating conditions of the thyraton. The omission of this delay line, therefore, has no effect upon the operation of the circuit of Figure 9.

A pulse, whose delay with respect to the fixed pulse may be varied, is provided by the pulse generator. The delayed pulse is amplified by the *6V6* (4) and its output (a negative pulse) also drives the grid of tube 5. This negative pulse, superimposed upon the positive pulse already present on the grid of the *807* (5), serves to reduce or to stop entirely the flow of plate current in tube 5. The delay line then may recharge to the *B* supply potential or to whatever voltage less than the *B* supply voltage, amplifier 5 holds the anode of the thyratron.

Thus, for any given time after the thyratron has been ignited, its anode voltage may be increased until it is reignited. A graph of the maximum plate voltage which just produces reignition versus microseconds after initial ignition (a deionization-time curve) can be plotted. During the interval between ignition of the thyratron and its subsequent reignition, the anode is maintained at a potential of 20 volts below that of the cathode.

The time interval between ignition of the thyratron and its subsequent reignition was measured by simultaneously displaying upon a 5-inch oscilloscope screen, the fixed pulse, the delayed pulse, and a sweep marker wave form consisting of the oscillations of a shock-excited tuned circuit. The sweep generator supplied the oscilloscope with sweeps of 5 microseconds, 25

microseconds, 100 microseconds, 500 microseconds, and 2,000 microseconds with marker wave forms for each sweep. Each marker wave form consisted of 10 oscillations of a shock-excited tuned circuit, the time of one oscillation equaled 1/10 the duration of the sweep. The measurement could be obtained with a precision of 1/4 the time of an oscillation, or about 10 microseconds on the 500-microsecond sweep. Consequently, when observing the wave forms on a 500-microsecond sweep, no attempt was made to compensate for the error introduced by the sloping test pulse (wave form of the charging delay line) since this was small as compared to the possible error involved in estimating the time interval between the fixed and delayed pulses. Depending upon the voltage at which reignition occurs, the time delay in attaining this voltage may range from zero to several microseconds at 400 to 500 volts. When faster sweeps were employed (less than 100 microseconds in duration) and the precision of the measurement approached the magnitude of the error introduced by the sloping test pulse, another method of observation was employed wherein the sloping test pulse was displayed and its time of rise could be estimated.

Three tube types, the *884*, the *2050*, and *2D21* were subjected to deionization-time tests. The relevant characteristics of these tubes and the results of the tests are given in Table II.

The deionization-time characteristics of four thyratrons, type *884*, are shown on Figure 10. The biases indicated were obtained by biasing each tube 6 volts in excess of that required to prevent breakdown. The deionization-time characteristics of six thyratrons, type *2D21*, are shown on Figure 12. The numbers refer to the tubes and not to the curves.

Table II

Tube Type No.	Number of Electrodes	Gas	Gas Pressure, Microns	Reference
884	Triode	Argon	250	Figure 10
2050	Tetrode	Xenon	180	Figure 11
2D21	Tetrode	Xenon	150	Figure 12

The effect of variation of peak current upon the deionization-time of thyratron number 4, type *2050*, (shown on Figure 13) was determined by using delay lines of different characteristic impedances and corresponding cathode resistors.

The variation of the deionization time of thyratron number 4, type *2050*, as a function of grid resistance and anode voltage after ignition is shown on Figure 14.

The deionization-time variation of thyratron number 4, type *2050*, as a function of control grid bias is shown on Figure 15.

The effect of control grid and shield grid biases on the deionization time of thyratron number 4, type *2050*, is shown on Figure 16. The four curves plotted are to be compared by pairs. In each pair the

E_{v2} biases are different but have been adjusted to provide approximately the same trigger sensitivity.

The effect of ambient temperature on the deionization time of thyratron number 4, type *2050*, is shown on Figure 17.

The effect of the variation of pulse width (from 0.6 microsecond to 3.5 microseconds) upon the deionization time of the *2050* thyratron 4 is not shown. The variation of the pulse width over this range resulted in a slight increase in the deionization time of the tube for the wider pulses. The change in deionization time was so small that a single curve would represent the measurements if plotted on a scale similar to that of Figure 15. The precision of the measurement did not warrant a plot on an expanded scale.

The variation of deionization time of thyratron 2, type *2D21*, as a function of peak current, is shown on Figure 18. The peak current was varied by a procedure identical with that used in obtaining data for Figure 13.

The effect of variation of the ambient temperature on thyratron 2, type *2D21*, is shown on Figure 19.

Performance of Pumped Ignitron Rectifiers

C. C. HERSKIND
MEMBER AIEE

E. J. REMSCHEID
MEMBER AIEE

A LARGE NUMBER of mercury-arc rectifiers of the pumped-ignitron type have been installed since 1940 in electrochemical, industrial, and railway service. During the peak of the war effort, mercury-arc rectifiers accounted for over 15 per cent of the industrial power consumption in this country. They still form quite an appreciable percentage of the industrial power load, and the number of new installations is growing.

Rectifiers have established notable records for reliable and trouble-free operation comparing favorably with other types of power equipment. These have been quite fully reported in a number of excellent papers recently presented by users. The purpose of this paper is to review some of the operating records which are available in order to set forth a more comprehensive picture of rectifier performance, considering both that obtained in service to date and that which can be realized in the future by making full use of recent improvements.

This survey reviews the performance of pumped ignitrons rated 1,000 kw and above, at 250 and 600 volts as applied for railway, electrochemical, and industrial service. It covers the rectifier and its immediate auxiliaries, such as, evacuating, temperature regulating, and excitation equipment.

The quality of the performance of any apparatus may be judged by its ability to provide continuous service, the materials and labor required to maintain it in good repair, and its life.

Paper 48-35, recommended by the AIEE electronics committee and electronic power converters committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26-30, 1948. Manuscript submitted November 20, 1947; made available for printing December 10, 1947.

C. C. Herskind and E. J. Remscheid are both with the power rectifier engineering department, General Electric Company, Schenectady, N. Y.

The development of equipment capable of attaining a high order of reliability is based on the following principles

1. The apparatus must be of such character that sudden failures are a very rare or infrequent occurrence, and progressive deterioration occurs at a low rate.

2. If sudden failure is to be avoided, the process of deterioration must be observed and measured so that failure may be anticipated and corrective action taken.

3. If low maintenance is to be realized, the rate and extent of deterioration must be minimized.

These principles are a useful guide in evaluating performance.

Performance Records

Operating records are usually sketchy and incomplete, as they are primarily descriptions of the troubles experienced. They may not cover all the factors which must be considered in a full evaluation of performance. In an endeavor to bring all the factors into a true perspective, the operating data was analyzed in accordance with the following outline

1. Duty—type of service; operating voltage; current loading; amount of phase control.

2. Reliability—interruptions (number of arc-backs); availability (time out of service).

3. Replacements—rectifier tanks (parts); rectifier tank reconditioning; auxiliaries.

4. Preventive maintenance—grade of maintenance.

Operating data for more than 20 installations totaling over 260 rectifiers were analyzed. Table I shows the duty on these rectifiers, and the record of interruptions caused by arc-back.

Duty

The duty on a rectifier depends primarily on the voltage, current, and the amount of phase control. Values for these factors are given in Table I. The duty imposed by the commutating action must also be considered in a complete description of the duty. Calculations show that in the installations covered by Table I, the commutating duty when operating with no phase control is approximately as shown in Table II.

Phase control increases both the initial inverse voltage and final commutation rate in the same ratio. For these rectifier installations, the use of phase control increases the commutation duty by the following amounts:

Phase control (% reduction in voltage)	5—10—15—20—25
Commutation duty (% increase)	30—50—65—78—90

The commutation duty may be reduced by the use of commutating reactors. One of the installations is so equipped.

The duty on the rectifier also depends on the magnitude and duration of fault currents to which it is subjected. These

NOTES: (1) SERVICE PERIOD SHOWN BY UNDERSCORING
(2) UNIT EQUIPPED WITH COMMUTATING REACTORS

are determined by circuit constants and by the type of switchgear employed. No attempt has been made to cover this factor in the rectifier duty as the records of these installations indicate that adequate switchgear has been provided in so far as the rectifiers are concerned.

The class of service is another factor in duty. In railway service, the average current loading is usually less than a half of the continuous rating, but the rectifier is subjected to short time overloads of considerable magnitude. In electrochemical service, the load is constant and approaches the continuous rating of the unit. Industrial rectifiers carry a variable load having an average value about three-quarters of the continuous rating and occasional overloads of moderate value.

Reliability

The reliability of a rectifier may be measured by the number of interruptions in service arising from sudden failure, and the percentage of time it is available for service.

One of the principal and unique causes of interruption in continuity of the rectifier operation is arc-back. While arc-back does not usually cause permanent damage to the rectifier, its random and unpredictable occurrence presents a problem which requires special consideration. For example, where uninterrupted operation of d-c load is required, the rectifier installation must be designed so that only a part of the equipment is taken out of service during arc-back; the remainder remains in operation. While continuity of operation is obtained despite random arc-back, practical considerations require a low arc-back rate, as frequent arc-backs increase the duty on transformers and switchgear, thereby increasing the probability of their failure and shortening their life. Maintenance of circuit breakers is also increased. Furthermore, the random and unpredictable occurrence of arc-back increases the problems of the operating staff and the probability of mistakes in switching.

Arc-back rates for 19 installations are given in Table I. The period of operation covered by these records is shown by the heavy line underscoring each record. Where no values are given during the operating period, the records are not available.

The high arc-back rate experienced on some of the electrochemical installations during initial operation was caused by a faulty design which permitted liquid mercury to flow out of the exhaust line and strike the anode. Extensive field and factory tests were made in order to determine the cause of the arc-backs and the trouble was finally diagnosed in the middle of the year of 1943. The trouble was corrected by installing an improved baffle in front of the exhaust opening to prevent returning mercury from striking the anode. The drastic improvement in operation resulting from installation of these baffles is shown by Figure 1, which present a record obtained on a large installation. Some installations have been completely fitted with these improved baffles. On others, only the tanks with high arc-back rates have been so equipped. As a result, these latter installations show a higher arc-back rate than could otherwise actually be realized.

The arc-back records on the rectifiers in industrial service are incomplete. While no arc-backs are indicated in Table I, some have occurred during the initial operation of some of these units. However, arc-backs are so infrequent and are usually of so little consequence that no effort is made to keep accurate records.

The arc-back records given here probably tend to be pessimistic since full records are usually kept on units giving trouble while units which are operating without incident are forgotten. High arc-back rates are, of course, undesirable and tend to become a prime factor in rectifier performance. When the arc-back rate is below 2 or 3 per year per rectifier, it becomes a relatively unimportant factor and maintenance costs assume a dominant role.

From the point of view of reliability, arc-back stability is an important consideration when a rectifier is operating with a high arc-back rate. If the arc-back rate is not stable but tends to increase under such conditions, the unit may rapidly become inoperative. Experience has shown that pumped rectifiers may be operated with a high arc-back rate without rapid progressive deterioration. When one of the large installations reported here was put first into service, arc-backs occurred at a rate exceeding one arc-back per rectifier per day. Various causes contributed to this high rate, perhaps the most important of which was the presence of fine ceramic particles. The trouble was soon corrected and the installation has since operated with a very low arc-back rate.

Availability

There is no standard procedure for determining availability and so it does not therefore, furnish an accurate measure of rectifier performance. Availability is generally defined as the percentage of elapsed time that the unit is available for service. However, different users have different maintenance procedures and operating practices. Some users never take the unit out of service unless required for repairs while others have a definite maintenance procedure which may take the unit out of service for a considerable percentage of time. Reports on some rectifiers in electrochemical and industrial service claim 100 per cent availability. On the other hand, an availability of 92 per cent has been reported for some units in railway service which are giving good performance but are

taken out of service for long periods of time to fit a work schedule.

Replacements

It is difficult to determine accurately the annual replacements for the average rectifier unit. Reports from different installations vary widely with some showing operation of a single rectifier for several years with no replacements, while others indicate unusual failures not previously experienced. All reports indicate that the number and cost of replacements is very low.

Figure 2. Ignitor performance records

Curve *A*—Percentage of installed ignitors still in service

Curve *B*—Percentage of installed ignitors which failed in service

Curve *C*—Percentage of installed ignitors replaced by improved ignitors before failure

Reports for some electrochemical installations indicate total annual replacements for 12 rectifier units consisting of a few small components, such as, water pump bearings, heaters, electrolytic leads, and excitation circuit components (reactors, capacitors, and rectifiers). Failures of major items such as tanks, seals, and vacuum pumps occur but rarely.

Ignitors

Data covering ignitor performance are shown on Figure 2. These data were obtained from records covering over 800 ignitors installed in rectifiers operating in all three classes of service. The records show a large number of ignitor replacements but the causes of trouble have been corrected and the high replacement rate is not expected to recur.

Referring to Figure 2, curve *A* shows the percentage of ignitors installed during each of the past seven years which are still in service. All ignitors installed during the past three years are still in service. Many of the ignitors installed four and five years ago have been replaced with new ignitors of improved design. Practically all of the ignitors which were installed six years ago were in rectifier applications involving moderate duties. The curve shows that most of these are still in operation.

Curve *B* shows the percentage of ignitors which actually failed after the respective years in operation. Ignitors of the improved design have all survived three years of operation.

Curve *C* shows the percentage of ignitors replaced by new ignitors of improved design. These ignitors did not fail in service.

Poor ignitor performance was experienced on some of the large electrochemical installations. Studies indicated two causes of failure. One of these was the loosening of the ignitor in its metal support. Since the ignitor operates at 900 degrees centigrade, this mount must be designed to withstand high temperatures. The mechanical troubles were overcome by the substitution of suitable metals having an expansion coefficient near that of the ignitor material. The other was the wetting of ignitors by aluminum and other metals dissolved in the mercury. This was traced to the starter gasket. The source of wetting material was found to be the aluminum gasket at the starter opening. This trouble was corrected by replacing the inner aluminum gasket by a gasket of plastic material (Formar) which is not attacked by the mercury. The records show that no ignitor failures have occurred since the installation of the improved ignitors and gaskets. The ignitor and gasket changes were made at the time of installation of the improved exhaust baffle.

Reconditioning

The necessity for and the frequency of regular reconditioning of pumped ignitrons has not yet been fully established. The present practice is to recondition rectifier tanks when their operating records show an increasing or undesirable arc-back rate.

At the present time, reconditioning is not fully defined and as a result it is difficult to evaluate data from operating records. For example, it is possible to replace an ignitor or install a splash baffle in a pumped ignitron tank in less than one hour and put the tank back in service without degassing. As only one small part has been changed and the tank has not been degassed, this should not be considered as a reconditioning operation.

Since reconditioning of a rectifier tank requires appreciable time and may be an important item in maintenance costs, it is proposed that it be defined as follows: Reconditioning of a rectifier tank is a complete overhaul followed by degassing. A typical reconditioning procedure consists in opening the tank by removing the cover and starter, checking all internal parts, replacing any which are defective, replacing the ignitor if it shows evidence of wetting or erosion, brushing down the tank walls, replacing the old mercury with new clean mercury, installing new gaskets, replacing cover and starter, and finally degassing the tank.

The operating records indicate that pumped ignitrons incorporating the latest improvements can be expected to operate over 5 years without reconditioning. Further operating experience must be obtained to determine the average service life before reconditioning.

Corrosion

Pumped ignitrons are almost invariably provided with a recirculating cooling system using water for the cooling medium. Where the rectifier tanks and their water jackets are of steel, corrosion may be a

Table II

Service	D-C Volts	D-C Amperes Per Tank	Initial Inverse Volts	Final Commutation Rate Amperes Per Micro-Second
Railway	600	416	500	3
Electrochemical	600	416	600	2
Electrochemical	600	666	600	3
Industrial	250	500	250	3

serious menace to the life of the equipment when raw water is used as a coolant. It has been found that corrosion can be eliminated by adding less than 1/2 of 1 per cent of anhydrous sodium chromate to the recirculating water. Operating records covering more than 15 years show that when sodium chromate is properly applied and maintained, corrosion is effectively prevented.

Preventive Maintenance

Preventive maintenance is a program or the prevention of sudden failure by the maintenance of favorable conditions and the control of deterioration. It is based on occurrence of deterioration as a gradual process subject to observation. Since inadequate maintenance affects the condition of the equipment and the probability of failure, performance is dependent in some degree on the grade of maintenance.

A thorough maintenance program is standard practice on large installations as there is usually sufficient work to require the full time of a small crew. In small installations with one or two rectifiers, maintenance is usually done in a less systematic manner as it requires only part time of the maintenance crew and is done at times when other duties permit.

Summary

Operating records indicate that rectifiers equipped with the latest improvements can be expected to perform as follows:

1. Arc-back rate of less than 1 or 2 arc-backs per rectifier per year.
2. Average ignitor life exceeding 5 years.
3. Service life on rectifier tank exceeding 5 years, without reconditioning.

Railroad Electrification Energy Conversion and Transmission Costs

R. L. KIMBALL
ASSOCIATE AIEE

J. G. HOLM
MEMBER AIEE

Synopsis: Railroad electrification is now being considered in several sections of the United States. Questions regarding choice of power supply, design and cost have prompted an analysis of these problems on a two-track railroad of moderate traffic density. The scope covers features from utility supply to locomotive pantograph, including conversion apparatus, substations, and transmission. Locomotives are not included. A 330-mile section of railroad is used with trackage and traffic density closely resembling an actual case. A-c and d-c power systems are analyzed and compared. The a-c system is single-phase 25-cycle, with 24-kv trolley and 72-kv feeder-to-trolley voltages. Rotating frequency changer sets are used for conversion, supplying loads resulting from motive power equipped with single-phase motors, with or without power-factor corrective equipment, or with motor generators. The cost of conversion apparatus is considered separately, as it might be financed either by the railroad or utility. The d-c system uses 6-kv trolley voltage, with supplementary feeders. Metal-tank mercury-arc rectifiers are provided for conversion. Wood poles support all electrical circuits in both cases. Traffic densities are considered for 1940 and 1944 levels, the latter 57 per cent greater than the former. Cost estimates are based on 1939 price levels. The results show:

1. Traffic density is one of the controlling factors of cost of railroad electrification, but reasonable cost per annual thousand gross ton-miles can be obtained for a railroad handling moderate traffic.

2. The conversion and transmission requirements of electrification, carefully engineered, result in an annual cost of approximately 40 cents per thousand gross ton-miles, varying somewhat with the density of traffic.

3. A-c and d-c power systems are economically comparable on an electrification such as that studied herein.

4. The information presented herein is believed to be sufficient for making comparisons with present railroad operating costs and for assisting railroad management in estimating the value of electrification as a solution to the many complex problems that are demanding attention today.

5. There is no general solution to a railroad electrification problem; a thorough analysis of each particular case is required.

POSSIBLE lower electric power cost relative to fuels now used for motive power is directing considerable attention to additional railroad electrification in the United States. With the already recognized economies and advantages of electrification, coupled with the increase in economies by lowered electric power cost and reduction in capital cost by design consistent with conditions, electrification becomes increasingly attractive. Although economic comparisons between electrification and dieselization are beyond the scope of this paper, the relative trend of energy and fuel costs, just referred to, as well as the desirability of conserving rapidly diminishing national resources, favor electrification. This should give railroad management a stimulus to undertake studies of its possibilities.[1]

For illustration, an analysis has been made of a theoretical railroad handling moderate traffic which is representative of a number of nonelectrified railroads in the United States. Cost comparisons are based upon suitable designs of reasonably low capital cost. Electric energy is assumed to be purchased.[2] To the annual costs derived from this analysis must be added the cost of purchased electric power, which has not been included and which varies from four to six mills per kilowatt-hour at 60 cycles depending on local conditions and forms of contract. The economic results obtained are not presented as a generalized solution of the broad problem, but indicate the magnitude of capital and annual costs. In an actual case of a proposed railroad electrification, detailed study of the particular problem must be made. From the data presented, however, comparisons can be made with present operating costs.

Paper 48-37, recommended by the AIEE land transportation committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted March 21, 1947; made available for printing December 15, 1947.

R. L. KIMBALL and J. G. HOLM are both with Gibbs and Hill, Inc., New York, N. Y.

In the preparation of this paper extensive use has been made of data and experience accumulated by Gibbs and Hill, Inc., in past railroad electrification. Due acknowledgment is made to the clients of Gibbs and Hill, Inc., and to the manufacturers of electrical apparatus that have contributed information.

SCOPE

Either a-c or d-c electrification has advantages compared with other motive power and, therefore, both are considered. The a-c system is 25-cycle single-phase, with rotating frequency changers to convert from the 60-cycle energy normally supplied by a utility. These conversion units supply power to either of two types of motive power: equipped with single-phase series motors, operating at 85 per cent power factor lagging; or with either motor-generator sets operating at 95 per cent power factor leading, or series motors whose power factor is corrected sufficiently to obtain a similar leading power factor. The two cases are identified as 85 per cent lagging and 95 per cent leading without reference to the particular type of locomotive. The d-c system uses metal-tank mercury-arc rectifier units to supply traction requirements from corresponding 60-cycle sources.

A 24-kv trolley voltage for a-c and 6-kv for d-c electrifications have been selected. They are higher than voltages now in general use, but are more moderate than the 48-kv for a-c and 15-kv for d-c systems that have been considered. This selection is justified by operating experience in the case of 24-kv a-c and by general progress in the design of d-c equipment.

For each system two traffic densities are assumed corresponding to 1940 and 1944 levels designated 100 per cent and 157 per cent traffic, respectively.

Costs are developed for each system on 1939 prices which are considered the most recent stable basis for comparison.

Cost of signal changes, electrolysis mitigation, changes in alignment road-

way, bridge, and tunnel clearances have not been included because they cannot be generalized. Provision for inductive coordination has been included to the extent of eliminating a-c stub-end feed under fault conditions and of providing at least a normal 24-phase d-c rectifier operation. To simplify analysis, expenditures for changes in such existing facilities have not been evaluated in the cost estimate. On the other hand, this study does not include major savings obtained from electric operation and the intangible factors of appeal. These savings, shown by experience to be of the order of 67 per cent reduction in locomotive maintenance when compared with steam operation, 25 per cent reduction in train and engine-crew costs, 75 per cent reduction in engine-house expense; together with smaller number of locomotives required, practical elimination of cost of water and maintenance of fuel and water stations, decreased maintenance on wheels and brake shoes due to advantages secured by regeneration, and absence of possible smoke and diesel-fume abatement expenditures, more than compensate for the expenditures omitted from costs, and are, in fact, the elements making railroad electrification economically attractive.

Figure 2. Diagram of electric supply circuit. A-c electrification

Description of Trackage Electrified

The theoretical 330-mile railroad chosen for analysis, and shown in profile in Figure 1, has trackage and traffic conditions closely resembling an actual steam-operated road. Average grades are approximately 0.8 per cent, with maximum and ruling grades of 1.2 per cent. Average curvature is approximately two degrees. The profile and compensated grade resistance in both directions of traffic are also shown on the figure. The total track mileage, laid with 115-pound rail, consists of 136 miles of single track (92 miles of which are two parallel single tracks on separate rights-of-way), 240 miles of double track, 44 miles of three track, and 45 miles of trackage in yards.

Character of Traffic and Characteristics of Motive Power

Total annual traffic density is taken at 6,065,600 thousand gross ton-miles at 100 per cent traffic and 9,524,000 thousand gross ton-miles at 157 per cent. These figures consist of 947,000 thousand gross ton-miles of passenger and 5,118,500 frieght at 100 per cent and 1,093,600 passenger and 8,431,000 freight at 157 per cent. In the analysis, the passenger and freight gross ton-miles are combined and treated together. The maximum number of daily freight trains to handle this traffic in each direction is 13 and 20 for the two traffic levels, when the ratio of maximum to average daily traffic is 1.5. The proportion of traffic moved in each direction is fairly well balanced in each section. The annual freight tons hauled from F to B are approximately 80 per cent of the freight hauled from B to F and the tons moved between A and B are the same in each direction. Passenger traffic is the same in both directions, six trains being scheduled each way.

Substation apparatus ratings and hourly power demands are based on fleets of trains moving simultaneously in both directions. For 100 per cent traffic each of these fleets consists of four trains, and for 157 per cent—of five trains. In both cases the spacing between trains is 18 miles and the fleets are preceded and followed by uniform train movements every 40 miles. Thus "bunching" of trains for the two traffic levels takes place over 54 and 72 miles, respectively. Because the system must be designed to handle peak movements, an advantage

Figure 3. Schematic diagram of substation spacings. A-c electrification

accrues to electrification in having sufficient capacity to handle increased traffic represented by added trains between peak movements. This is one of the reasons electrifications have so successfully handled unexpected traffic increases, such as have occurred during wartime.

In freight operation the rating of the interchangeable freight and passenger electric locomotives is 3,600 tons, representing a 30 per cent train consolidation compared with the usual steam operation for this traffic.

Alternating-Current Electrification

Electric Supply Circuits and Substation Spacing

The electric power conversion apparatus comprises rotating frequency changers installed at main substations fed through step-down transformers from the 3-phase 60-cycle utility power-supply lines. These conversion stations in turn feed 3-winding, single-phase 25-cycle power transformers supplying the feeder and trolley circuits. Autotransformer stations, connecting the trolley and feeder with the rail, are placed between main substations to maintain 24 kv on the trolley and 72 kv on the feeder circuit. This is shown in Figure 2.

This design eliminates the necessity of separate single-phase transmission lines paralleling the track and uses the autotransformers to obtain the desired voltage between trolley and rail.

The distance between autotransformer stations is theoretically determined by the allowable voltage drop in feeder and trolley circuits. Studies of 20, 30, 40, 50, and 60-mile spacings indicate that 30-mile spacing provides a reasonable margin in voltage drop for the location of autotransformer stations adjacent to crossovers or interlocking plants, and insures voltages above the 18-kv minimum considered advisable. With the 30-mile spacing and the feeder and trolley sizes used, the minimum delivered voltage at the locomotive is slightly over 20 kv. With 95 per cent power factor leading, a delivered voltage in excess of 21 kv is obtained with all autotransformer spacings. However, economic considerations and operating requirements, such as the maximum desirable length of track out of service at time of fault, indicate the choice of 30-mile spacing for both cases. A schematic diagram is shown in Figure 3.

Figure 4. Arrangement of switching equipment at substations. A-c electrification

Electric Power Requirements and Apparatus

Demands per train measured at the trolley on the A to D and D to F sections of the road are 7,500 and 5,000 kw, respectively, indicated in Figure 1, on which operating speeds are also shown. Load curves for the assumed train movements show maximum 1-hour average demands per conversion station of approximately 60,000 and 73,000 kw for the two levels of traffic. The combined maximum one-hour average demands for the system are approximately 199,000 and 218,000 kw, respectively. Proper allowances for efficiency, power factor, and varying load demands are made in determining the size of power apparatus. Spare capacity of each type of apparatus is provided in the conversion stations and at each autotransformer station. All transformers are capable of operation at 150 per cent load for two hours, and frequency changers can operate continuously at 115 per cent of nominal rating without further sustained overload capacity.

As the train fleet represents a moving load whose peak demand passes from one main substation to another, the total kilowatt capacity of frequency changers is reduced by interchange of power between adjacent conversion stations. At times of outage of a frequency changer the deficiency in capacity at that location is met by the adjacent conversion station on one or both sides. The simultaneous load on such conversion stations adjacent to a peak-loaded station is conservatively taken at 75 per cent of their own maximum peaks. This transfer is restricted to kilowatt flow, with practically firm reactive capacity being provided in each conversion station. Under this condition,

with both feeder systems in operation, no excessive voltage drop occurs.

The electrical apparatus required for the entire a-c electrification consists of 12 frequency changers, 13 3-winding power transformers and 24 autotransformers. Although the number of units remains the same for the various conditions of traffic and power factor of the load, the total installed capacity of each varies as shown in Table I.

Trolley-Feeder Circuits and Supporting Structures

Two separate trolley-feeder circuits are provided between adjacent substations, at each of which the circuits are sectionalized. The trolley system consists of a messenger of 400,000 circular mils copper equivalent with a contact wire of 300,000 circular mils 80 per cent equivalent conductivity. The feeders, capable of handling the entire traffic load with one feeder out of operation, are 350,000 circular mils and 250,000 circular mils for the 85 per cent lagging and 95 per cent leading cases, respectively.

The diagram in Figure 4 shows the arrangement of circuit breakers in the trolley-feeder circuits at main substations. A similar arrangement is employed at autotransformer stations. At station *A* where four power transformers are required, two are located on each side of the tie-circuit breakers, one per trolley-feeder circuit.

During normal operation the capacity of all transformers is available to any or all trolley-feeder circuits. This connection of feeder and trolley circuit breakers, in conjunction with a power-transformer primary circuit breaker where necessary, permits de-energizing any transformer and disconnecting it by means of horn-gap switches. Upon loss of one trolley and its load between two substations, 75 per cent of the transformer capacity remains available for the reduced load. Fault clearing is accomplished by automatic circuit-breaker operation arranged to leave an autotransformer temporarily connected to each end of the faulted circuit. In this way stub-end feed to a fault is avoided. Phase breaks are placed at three autotransformer stations, one between each of the main supply points.

Experience shows that wood poles are suitable for this type of electrification, materially reducing the initial capital investment. Each structure is a class 3 pole, approximately 50 feet long, carrying one 1/0 copper ground wire, a feeder wire and the contact system. Seven 10-inch disk insulators are used to support the feeder wire. There are assumed to be 31 structures per mile, of which 40 per cent are located on tangent. No provision, other than strength of pole and available space, is made for signal circuits.

Table I

	85 Per Cent Lagging Power Factor		95 Per Cent Leading Power Factor	
	100 Per Cent Traffic	157 Per Cent Traffic	100 Per Cent Traffic	157 Per Cent Traffic

Direct-Current Electrification

Electric Supply Circuit and Substation Spacing

Conversion apparatus consists of metal-tank mercury-arc 12-phase rectifiers, supplied through rectifier transformers from the 3-phase 60-cycle utility power supply. Nominal 6,000 volts are maintained at the rectifier terminals.

Voltage regulation and economics permit the location of main rectifier stations at 60-mile spacing with end substations located 15 miles from each terminal. This substation spacing, with the selected feeder and trolley conductivities, provides a minimum of approximately 4,650 volts at the train with maximum traffic concentration, corresponding to an average voltage drop of about 11 per cent. The two supplementary feeder and trolley systems are connected electrically at the quarter- and mid-points between substations by intermediate tie stations having a common bus, as shown in Figure 5.

Power Requirements and Apparatus

Power requirements are estimated to be 7,040 and 4,700 kw input to the train on

Table III. Typical Calculation of Total Capital Cost. D-C Electrification. Case of 157 Per Cent Traffic

(Cost in dollars)

Cost of money during construction	692,200	14,536,400
Total Capital Cost		29,719,600

the A to D and D to F sections of the profile respectively.

Train movements, previously described, require 165,000 kw of rectifier capacity for 100 per cent traffic and 178,000 kw for 157 per cent. The same size units are used at each substation, 7,500 kw for 100 per cent traffic and 8,000 kw for 157 per cent; and there are four units at each substation, except at e and f where there are three.

The maximum one-hour average demand is approximately 146,000 kilowatts for 100 per cent traffic and 150,000 kilowatts for 157 per cent.

The substations include phase shifters for basic wave-shape correction which will presumably meet all except the most unusual requirements of inductive coordination.

Trolley and Feeder Circuits and Supporting Structures

Similarly to the a-c electrification, two separate trolley and supplementary feeder circuits are provided. The trolley system consists of a messenger of 500,000 circular mils copper equivalent and of two contact wires of 300,000 circular mils 80 per cent equivalent, per track. Each supplementary feeder is 1,000,000 circular mils copper.

The arrangement of circuit breakers at the main and intermediate tie substations is shown in Figure 6. No phase breaks are required.

The wood-pole supporting structures are the same as those used in a-c electrification, except that heavier feeder and catenary systems require a class 2 pole. The same 1/0-size copper ground wire is used.

Cost Comparisons

Method of Estimating Capital Cost

For estimating the capital cost of the conversion and transmission requirements of electrification, the system is divided into the following groups:

1. Main substations
2. Autotransformer substation, or tie substations
3. Feeder and trolley circuits and supporting structures, including rail bonding

Typical calculations of capital cost for both a-c and d-c systems are given in Tables II and III, respectively.

The cost of all apparatus and material delivered to the site is developed from manufacturers' estimates. To these costs are added percentages covering labor, construction-equipment rental, and indirect expenses. The labor percentages were determined from experience on actual electrifications and vary with the type of apparatus. Indirect expenses cover the following: engineering expenses, field superintendence, legal expenses, taxes, insurance during construction, and normal contingencies. To cover indirect expenses, $22^1/_2$ per cent is added to the delivered and erected costs. Money is taken at four per cent for $1^1/_4$ years which is one half of the assumed construction period. This method of cost estimating is described in greater detail in a paper written by one of the authors.[3] Should it be desirable to modify either the indirect expenses or the length of the construction period, changes can be introduced easily in the capital cost figures.

Capital Cost of A-C Electrification

Total capital costs of the four cases of a-c electrification are given in Table IV.

These costs are separated into the three major divisions in Table V.

The value of locomotive power factor improvement is readily seen. The effect of traffic density is also evident, the 57 per cent greater traffic requiring an increase of only one per cent in total capital cost which in turn produces a decrease of about 36 per cent in cost per thousand gross ton-miles. This is because the maximum concentration of trains which may occur does not differ greatly for the two annual traffic conditions.

In some instances the utility is willing to assume the financing of the conversion stations in order to reduce the railroad's capital investment. The cost of such conversion stations accounts for approximately 40 per cent of the total cost of the power system, as shown in Table VI.

If it is assumed that the utility will

Table IV

	85 Per Cent Lagging Power Factor		95 Per Cent Leading Power Factor	
	100 Per Cent Traffic	157 Per Cent Traffic	100 Per Cent Traffic	157 Per Cent Traffic
Total	$25,198,200	$25,447,300	$23,118,400	$23,310,600
Per route-mile	76,300	77,100	70,000	70,550
Per track-mile	33,700	34,000	30,900	31,100
Per thousand gross ton-miles	4.15	2.67	3.81	2.45

Figure 5. Schematic diagram showing location of rectifier and intermediate tie substations. D-c electrification

install the conversion stations, the total capital expenditure of the railroad will be reduced accordingly but at the expense of the increased cost of purchased power.

Capital Cost of D-C Electrification

Total capital cost of the d-c electrification is given below:

	100 Per Cent Traffic	157 Per Cent Traffic
Total	$28,819,500	$29,719,600
Per route-mile	87,300	90,050
Per track-mile	38,500	39,700
Per thousand gross ton-miles	4.75	3.12

These costs are separated into the three major divisions as shown in Table VII. Cost of rectifier apparatus installed is assumed at $61 per kilowatt of capacity, including rectifiers, transformers, high-voltage circuit breakers, and protective and control apparatus. This figure does not include the costs of foundations and indirect expenses which have been added separately.

Similar to the a-c electrification, the effect of traffic density is evident, 57 per cent greater traffic requiring an increase of only three per cent total capital cost, which in turn produces a decrease of about 34 per cent in cost per thousand gross ton-miles. If it is assumed that the utility will install the main substations, that is, the rectifiers and transformers, switching and control apparatus, the total capital expenditure of the railroad may be reduced by about 48 per cent, to $13,555,900 and $14,456,000 for the two levels of traffic. Here again, this reduction is at the expense of the cost of purchased power.

Method of Estimating Annual Cost

Annual cost (exclusive of cost of purchased power) is the sum of annual fixed charges and annual operating expenses. Annual fixed charges cover taxes, insurance, depreciation, and interest on money invested. Annual operating expenses cover maintainance, operation, and cost of energy loss. Both annual fixed charges and annual expenses for maintenance and operation are calculated as percentages of capital cost for each of the three major groups into which the capital cost structure is divided. These percentages are the same for both a-c and d-c systems. The annual fixed charges amount to eight per cent, made up of one per cent for taxes, one-half of one per cent for insurance, two and one-half per cent for depreciation (on the basis of 40-year average useful life of apparatus) and four per cent for interest on money. The annual expense for maintenance and operation is two per cent for main substations, autotransformer and intermediate tie substations; it is three per cent for trolley and feeder circuits. Losses in rectifiers are considerably smaller than in frequency changers with their 3-winding transformers, for which an adequate allowance has been made. Comparisons are made for annual load factors of 30, 45, and 60 per cent.

Annual Cost of A-C Electrification

Annual costs derived from the capital costs given previously, but not including the cost of electric energy or annual locomotive costs, are as shown in Table VIII.

These costs are separated into the three major divisions as shown in Table IX.

The saving in capital cost by improving the power factor from 85 per cent lagging to 95 per cent leading is reflected here in a 10 per cent decrease in the annual charges.

Annual cost of the system necessary for the larger traffic is only slightly higher than that necessary for 100 per cent traffic but the annual cost per thousand gross

Table V. Capital Cost. A-C Electrification

(Cost in dollars)

Item Description	85 Per Cent Lagging Power Factor		95 Per Cent Leading Power Factor	
	100 Per Cent Traffic	157 Per Cent Traffic	100 Per Cent Traffic	157 Per Cent Traffic
Entire System				
Total cost	25,198,200	25,447,300	23,118,400	23,310,600
Cost per route-mile	76,300	77,100	70,000	70,550
Cost per track-mile	33,700	34,000	30,900	31,100

Main Substations				
Total cost	10,402,800	10,651,900	8,937,600	9,129,800
Cost per kw of installed frequency changers	48.3	44.5	41.5	38.2
Cost per 1,000 gross ton-miles	1.71	1.12	1.47	0.96
Autotransformer Substations				
Total cost	2,976,200	2,976,200	2,734,800	2,734,800
Cost per kva of installed autotransformers	10.33	10.33	11.40	11.40
Cost per 1,000 gross ton-miles	0.49	0.31	0.45	0.29
Feeder-Trolley Circuits—Main Line and Yards				
Total cost	11,819,200	11,819,200	11,446,000	11,446,000
Cost per route-mile	35,800	35,800	34,700	34,700
Cost per track-mile	15,800	15,800	15,300	15,300
Cost per 1000 gross ton-miles	1.95	1.24	1.89	1.20

Table VI

	85 Per Cent Lagging Power Factor		95 Per Cent Leading Power Factor	
	100 Per Cent Traffic	157 Per Cent Traffic	100 Per Cent Traffic	157 Per Cent Traffic
Conversion stations	$10,402,800	$10,651,900	$8,937,600	$9,129,800

ton-miles for the higher traffic is approximately 35 per cent lower. In other words, the energy conversion and transmission costs of an electrification do not vary directly with annual traffic because they are determined by the maximum concentration of movement and not by the average.

Should the utility assume the financing of the conversion stations in order to reduce the railroad's capital investment, the resulting annual interest payments by the railroad will decrease by approximately 40 per cent, at the expense of an increased cost of purchased power.

Annual Cost of D-C Electrification

Annual costs of d-c electrification have been determined in the same manner as

Table VII. Capital Cost. D-C Electrification

(Cost in dollars)

Item Description	100 Per Cent Traffic	157 Per Cent Traffic
Entire System		
Total cost	28,819,500	29,719,600
Cost per route-mile	87,300	90,050
Cost per track-mile	38,500	39,700
Cost per 1,000 gross ton-miles	4.75	3.12
Main Substations		
Total cost	13,555,900	14,456,000
Cost per kw of installed rectifiers	82.2	82.1
Cost per 1,000 gross ton-miles	2.24	1.52
Intermediate Tie Substations		
Total cost	727,200	727,200
Cost per 1,000 gross ton-miles	0.12	0.076
Feeder-Trolley Circuits—Main Line and Yards		
Total cost	14,536,400	14,536,400
Cost per route-mile	44,050	44,050
Cost per track-mile	19,450	19,450
Cost per 1,000 gross ton-miles	2.40	1.53

those of the a-c electrification and are as follows:

	100 Per Cent Traffic	157 Per Cent Traffic
Total per year	$3,456,100	$3,547,300
Per kwhr used at		
30% annual load factor	9.02 mills	8.97 mills
45% annual load factor	6.02 mills	5.98 mills
60% annual load factor	4.51 mills	4.48 mills
Per route-mile per year	$10,450	$10,750
Per track-mile per year	4,620	4,740
Per thousand gross ton-miles per year	0.569	0.372

These costs are also separated into the three major divisions as shown in Table X.

As in the a-c electrification the annual cost of the system for the larger traffic is only three per cent greater than for 100 per cent traffic but the annual cost per thousand gross ton-miles for the higher traffic is approximately 35 per cent less.

Utility financing of the main substations would reduce the annual interest payments by approximately 45 per cent at the expense of an increased cost of purchased power.

For 157 per cent traffic and assuming that the railroad finances the entire electrification, the capital costs per thousand gross ton-miles vary as follows:

A-c electrification 95 per cent leading power factor $2.45

A-c electrification 85 per cent lagging power factor $2.67

D-c electrification $3.12

Table VIII

	85 Per Cent Lagging Power Factor		95 Per Cent Leading Power Factor

Cost per route-mile per year	5,320	5,320	5,010	5,010
Cost per track-mile per year	2,350	2,350	2,210	2,210
Cost per 1,000 gross ton-miles per year	0.289	0.184	0.273	0.174

Comparison of A-C and D-C Electrification Costs

Comparison of costs of the two systems, to be correct, should be made on the basis of gross ton-miles moved rather than on the basis of cost per kilowatt-hour.

The foregoing figures given reveal that the two systems cost essentially the same.

The total annual costs, exclusive of cost of purchased power and that of the locomotives, for the same conditions per thousand gross ton-miles per year are as follows:

A-c electrification 95 per cent leading power factor $0.338

D-c electrification $0.372

A-c electrification 85 per cent lagging power factor $0.378

The total capital cost of the d-c electrification, at assumed rectifier unit prices is higher than that of a-c electrifications. This is due to the greater cost of feeder and trolley circuits, and supporting structures. On the other hand, the total annual cost of the d-c electrification is lower than that of a-c electrification at 85 per cent lagging but higher than that at 95 per cent leading power factor. This is due to smaller losses in the d-c system.

Summary and Conclusions

1. It is entirely feasible to design an adequate energy conversion and transmission system of reasonable cost for either a-c or d-c electrification of a railroad with moderate traffic density. The heavier the traffic or the grades the more economical electrification becomes.

2. For such a system the annual cost, exclusive of purchased power, is of the same general magnitude as the cost of this power. This should be considered as a very moderate price to pay for the greatly reduced maintenance and improved performance of electric motive power.

3. When the utility undertakes the capital expenditure for the main substations, the initial capital expenditure by the railroad is materially reduced, in return for which the railroad would have to pay a higher rate for electric energy.

4. The economy of railroad electrification depends to a large degree on the ratio of maximum to average traffic density.

5. By means of power interchange between conversion stations or the "peaking"-power transfer scheme in a-c systems, it is possible to reduce the spare frequency-changer capacity to approximately the capacity of one unit on the entire system.

6. In a-c electrification appreciable savings in capital and annual costs can be obtained by approaching a 95 per cent leading power factor at the locomotive.

7. Higher feeder and trolley voltages may produce further savings where the use of such voltages is indicated.

8. Capital and annual costs of d-c electrification will be lower than those submitted if the costs of rectifier units and other equipment decrease with further development. The present indications are that this will be accomplished.

9. Data in this paper are not intended a conclusive comparison of a-c with d-c systems but are presented to assist in estimating the economic results to be obtained by conversion to electric operation on a railroad of moderate traffic density. To obtain a definite comparison, regardless of traffic, it is necessary to consider not only the costs discussed but also operating expenses in connection with other major elements of electrification, such as cost of electric energy, of locomotives and the cost of modification of wayside installations. In any case of contemplated railroad electrification a thorough analysis of the particular problem is required.

10. The information presented is believed to be of sufficient scope and detail so that comparisons with present operating costs can be made, thus assisting railroad management to determine the value of electrification as a solution to their many complex problems.

Table X. Annual Cost. D-C Electrification

(Cost in dollars, except where indicated)

Item Description	100 Per Cent Traffic	157 Per Cent Traffic
Entire System		
Total cost	3,456,100	3,547,300
Cost per kwhr at		
30% annual load factor (mills)	9.02	8.97
45% annual load factor (mills)	6.02	5.98
60% annual load factor (mills)	4.51	4.48
Cost per route-mile per year	10,450	10,750
Cost per track-mile per year	4,620	4,740
Cost per 1,000 gross ton-miles per year	0.369	0.372
Main Substations		
Total cost	1,548,400	1,639,600
Cost per kwhr at		
30% annual load factor (mills)	4.04	4.14
45% annual load factor (mills)	2.69	2.76
60% annual load factor (mills)	2.02	2.07
Cost per kw of installed rectifiers per year	10.62	10.88
Cost per 1,000 gross ton-miles per year	0.255	0.172
Intermediate Tie Substations		
Total cost	72,700	72,700
Cost per 1,000 gross ton-miles per year	0.012	0.0076
Feeder-Trolley Circuits—Main Line and Yards		
Total cost	1,835,000	1,835,000
Cost per route-mile per year	5,550	5,550
Cost per track-mile per year	2,450	2,450
Cost per 1,000 gross ton-miles per year	0.303	0.193

Discussion

T. M. C. Martin (Bonneville Power Administration, Portland, Ore.): Whatever the intentions of Kimball and Holm in attacking the problem of electrifying the 330-mile section of railroad assumed in their paper the result is to establish beyond reasonable doubt the uneconomic nature of the solution offered. The average daily traffic, both passenger and freight, assumed by Kimball and Holm is only about 50,000 tons per day (for their 100 per cent traffic case) over the section including movements in both directions. This is to say that the railroad is one of "moderate traffic density." In the circumstances it can scarcely be presumed that such a railroad could indulge in the character of operations assumed by Kimball and Holm—operations which automatically inflate the capital costs of electrification by not less than 100 per cent. The assumed railroad is not a heavy grade operation, having a ruling gradient of a little less than 1.0 per cent. With such sparse traffic and such a relatively easy profile it is extremely disturbing to find the authors imposing schedule requirements that assure the worst possible load factors and consequently the least likelihood of achieving reasonable power costs. What is equally disturbing is the wide-open case made by such a presentation for the installation of Diesel-electric locomotives. The authors have implied a cost in round numbers of about $24,000,000 for this 330-mile section of electrification, entirely exclusive of motive power. The writer will hazard the guess that because the assumed method of operation involves very poor utilization, an additional investment of not less than $16,000,000 for motive power would be required, making a total investment of around $40,000,000 or about $120,000 per route mile.

The writer feels very confident that the application engineers of any of the Diesel manufacturers would find such a situation made to order. It seems certain that they would insist upon enough better utilization of motive power to enable them to dieselize this same section for a total expenditure of about $10,000,000, which amount would largely be expended for motive power.

The writer does not wish to leave the impression that he believes dieselization of such a section either desirable or inevitable. Quite the contrary he has been privileged to participate in a recent study looking toward the electrification of 350 miles of western main-line crossing the Cascade Mountains against ruling gradients of 2.2 per cent (more than twice as steep as those assumed by Kimball and Holm) and as a result thereof it is his firm conviction that such an electrification can be accomplished even under present prices with ample reserve capacities in both trackside power supply apparatus and motive power for about the following sums:

Power supply including trolley, transmission, trackside substation apparatus, and so forth	$12,000,000
Electric motive power	8,000,000
Total electrification capital cost	$20,000,000

This is less money for everything including motive power to operate against twice as rugged a profile, and it is based on actual operating practices of a leading western railroad. Finally from a power supplier's standpoint it is based upon realistic appreciation of the necessity of better electrical load factors as a prerequisite to more favorable operating costs so far as cost of electric power is concerned.

When appraising electrification possibilities it seems unwise for engineers to handicap electrification chances by assuming that it is necessary to provide trackside power supply apparatus capable of withstanding peak demands of twice the magnitude that could possibly be imposed by the simultaneous operation at full load of all the motive power units which normal efficient utilization would dictate as being the maximum number the railroad should purchase. For the purely main-line operations of the section assumed by Kimball and Holm it can be shown that about 60,000 continuous rail horsepower of locomotives would be entirely adequate to handle their 100 per cent traffic case. Were all locomotives taking full power the simultaneous substation demands would hardly aggregate more than 70,000 kilowatts. When it is remembered that to protect this possibility Kimball and Holm have suggested 240,000 kva of frequency changer capacity and correspondingly large aggregates of trackside substation capacity it will be realized that their conservatism has led them into a very considerable overinstallation of roadside equipment.

H. F. Brown (New York, New Haven and Hartford Railroad, New Haven, Conn.): The title of the paper by Kimball and Holm while justified by existing power generation conditions today indicates why the Diesel-electric locomotive enjoys its present economic advantage. I refer to the phrase "Energy conversion costs."

The Diesel-electric locomotive generates without further conversion the type of electric power required by the locomotive; at present almost exclusively direct-current but alternating-current with its additional advantages is already being carefully considered.

Why must the railroads purchase electric power for traction purposes in a form they cannot use, and then with its own investment, and operators, and maintainers, convert this power into a form they need? Naturally, the railroads would prefer not to be in the "power business," if they can purchase at reasonable cost the power they need; but if they have to do this with additional investment, mentioned in this paper as 40 per cent of the total investment exclusive of locomotives, and then have additional operating and maintenance expense, they might better go all the way and own and operate their own power station, because they are in the "power business," even if it is only for "conversion" and operation of conversion facilities.

The problems of owning and operating power plants are of no more magnitude than owning and operating converting stations, and the economies are very real. A pioneer single-phase eastern electrified railroad still operates its own 25-cycle power plant, which supplies about 55 per cent of its total requirements. It purchases about 40 per cent of 25-cycle single-phase power directly as such from a large utility which generates both 25 and 60 cycles with both systems tied together. It purchases about 5 per cent of its power at 60-cycles from another utility, paying all operating and maintenance costs in addition to power rates approximately equal to the equivalent 25-cycle block purchased directly from the other utility, and absorbs in so doing an average 18 per cent conversion loss. The "cost of conversion" indicates why a greater use is not made of the 60-cycle supply.

The power companies could develop a large and profitable base load, in time, if they would give more attention to this problem—a potential load which often parallels their own power networks. One or two large utilities generate both 25 and 60 cycles. The largest commercial hydro plant in Canada—the Beauharnois plant—has 5 of its 12 wheels generating 25 cycles, all feeding into Ontario.

The power utilities can be complacent and say "60-cycle power is standard for all uses, and if some other frequency is needed the customer will have to change it"; or they can be complaisant, and do much to encourage railroad electrification, as part of the general electrification of all industry, by generating the kind of power necessary for this potential business, which, all factors considered, could be 25 cycles regardless of the form of electrification used.

Just as power systems can profit by interconnection, so can railroads, with their own station or stations, interconnected with other power sources, profit by so doing, in the interchange of power during periods of wide diversity. This may involve additional conversion equipment, the cost of which could be shared, but of far less capacity than involved in the major supply.

Many of the earlier eastern electrifications, although some have leased their owned electric plants to the large power utilities in their area, are still profiting from having owned their own stations in their present power rates.

Power conversion costs, as such, should not be so great a charge against railroad electrification.

Kimball and Holm mention the economies of the 95 per cent leading power factor locomotives, without being specific as to just how this is accomplished. It is obvious that if the means used makes the motive power more expensive, that difference in cost will have to be subtracted from the economies realized in the transmission.

The choice of voltage, both alternating and direct current, tend to make this paper seem just a bit impractical. Surely, if 6-kv can be justified for the d-c electrification, 12-kv can be justified for the a-c study, and with the experience over the past four decades by the railroads with the largest amount of electrified mileage, and in the interests of standardization, the justification for the choice of these voltages does not seem to be clearly defined. Possibly a factor could be supplied in each case to show the saving accomplished by going to these higher voltages.

The paper specifically excludes locomotives and no estimate as to the number required is given, other than to state that they are used interchangeably in both passenger and freight service. Nevertheless, in the over-all economic picture they must be considered.

If it is assumed that between 20 and 35 will be required to take care of the assumed

traffic, and if it is assumed that electric locomotives will cost $300,000 each, a total investment, (in addition to that for the conversion and transmission facilities of between $23,000,000 and $29,000,000) of $6,000,000 to $10,000,000 will be required for locomotives. If it now be assumed that Diesel-electric locomotives could handle the service equally well, and that, for the same rail horsepower such locomotives will cost $500,000 each, the railroad management would have to decide whether to purchase between $10,000,000 and $17,500,000 worth of Diesel-electric locomotives, presumably with equipment-trust certificates, or to purchase, in the same manner, between $6,000,000 and $10,500,000 worth of electric locomotives, and then find some way of financing an additional investment of $23,000,000 to $29,000,000 in fixed property, a somewhat difficult task in these days for even the most prosperous railroads.

The difference in total investment between electrification and Dieselization is between $19,000,000 and $22,000,000. Even if it could be shown that electric operation could effect savings over Diesel operation to warrant this investment, the matter of financing would still be the deciding factor.

Sidney Withington (New York, New Haven and Hartford Railroad, New Haven, Conn.): Kimball and Holm mention the cost of purchased power as varying "from four to six mills per kilowatthour at 60 cycles." It would be interesting to know of any utility which would deliver power at such rates even under the most favorable load factor specified and even at 1939 costs. Evans sets up perhaps more realistic costs running from "0.5 cent to 2 cents per kilowatthour," depending on load factor and other considerations. Evans' power analysis gives hydro power system demand costs of 90 cents per kw per month, presumably integrated hour. This would inferentially represent power solely from a system which does not require any steam plant stand-by for use in dry periods or under flood conditions—a situation which does not occur in most sections of this country. It would be of interest to have more information on this.

It is indicated that the hypothetical railroad described has 90 miles of two single-track rights-of-way. The diagrams indicate that these two routes are supplied from the same d-c substation and that trolleys and feeders are tied together at 15-mile intervals at the substation, and that the a-c network ties them together at two intermediate points. A word as to the separation of these two rights-of-way would be of interest. Presumably there would be a 48-kv a-c feeder along each of these single track routes. A word on this would be interesting.

The demands per train at a maximum of 7,500 kw (integrated hour) indicate heavy motive power. The assumed figure of 37 kilowatthours per 1,000 gross-ton-miles (with locomotive 41 kilowatthours) seems somewhat low when compared with figures reported by existing railroads of this general class of service. It is presumed this is measured at the point of supply rather than at the shoes, but a word on this would be interesting.

In this connection it is not made clear why the demand per train for a-c varies between 5,000 and 7,500 kw and for d-c 5,000 and 7,040 kw, while the energy is greater for the direct-current system, all for the same train service.

It appears that for the single-phase supply, twelve frequency changers rated at 20,000 kw are contemplated at four substations, or 60,000 kw per substation. Evans states that "combining substations has no merit," though such combination he points out would save $229,000 per year in demand charges. Evans indicates that costs of transmission tying systems together would amount to $2,400,000 in addition to substation facilities at $20 per kilowatt. In view of the fact that the catenary supporting structures are available for high voltage circuits, a cost of $20,000 per mile for the 100-kv circuits seems generous, even at 1939 prices. Furthermore, with 48–24-kv single-phase tie circuits, considerable "combining of loads" would be practicable with the system as designed. Furthermore, it may be presumed these systems are tied in on the 60-cycle side by means of utility networks, and this would permit combining load through co-operation among the utilities. The power saving through combining loads in order that the railroad would not have to pay for the same demand twice might well affect the decision of the railroad whether or not to adopt electrification. Kimball and Holm indicate 8 per cent is sufficient estimate for railroad capital requirements, while Evans figures 10 per cent. The railroad would presumably be consistent in taking a uniform figure for all such capital expenditures

Evans suggests the railroad can save on its power bills by creating a diversity of its own by "providing for trains standing in sidings—and traveling partly loaded." This may be practicable on some railroads, but most roads must operate service when it is offered and as expeditiously as possible, and must handle trains of maximum practicable tonnage at all times. The power supply must be employed to operate the railroad most efficiently, and operation of the railroad to benefit the supply by careful dispatching of trains, as Evans suggests, is not popular with most railroad managements.

Kimball and Holm indicate that the utilities supplying power might be willing to install the frequency-changer or rectifier equipment. This would be a consummation devoutly to be wished from the railroad viewpoint, because most railroad organizations are not equipped for operating and maintaining substations of these kinds. It would be very doubtful, however, if, in figuring fixed charges for capital, any power company would be satisfied with return of 8 per cent, as indicated, to cover interest, depreciation, insurance, and taxes, and there would be, as implied, very considerable "increased cost of purchased power," which might change the analysis materially.

Kimball and Holm indicate that as between alternating and direct current the capital costs "are essentially the same," and they tabulate the data to show that a-c electrification capital costs are $2.45 and d-c electrification $3.12 per thousand gross ton miles, and that annual costs (exclusive of purchased power and locomotives) are $0.338 for alternating current and $0.372 for direct current (95 per cent leading power factor a-c electrification in each case). Evans shows that power bills for 157 per cent traffic with no diversity are 0.997¢ per kilowatthour for alternating current and 1.101¢ for direct current per kilowatthour. The advantage in this analysis would appear to rest with single phase.

Comparisons between systems of electrification are open to a vast amount of discussion, and any engineer who estimates relative costs and advantages is courageous indeed. Evans and Kimball and Holm are to be congratulated on their courage and their stimulating analysis of this complicated question.

K. H. Gordon and **L. B. Curtis** (Pennsylvania Railroad, Philadelphia, Pa.): The excellent paper prepared by Kimball and Holm is of current interest and should stimulate increased discussion of further electrification possibilities.

However, it is our opinion that the statement "The information presented herein is believed to be sufficient for making comparisons with present railroad operating costs and for assisting railroad management in estimating the value of electrification as a solution to the many complex problems that are demanding attention today," is unduly optimistic and gives questionable assurance that comparisons of sufficient and necessary accuracy can be made. It overlooks these factors:

1. Over-all cost comparisons between steam, electric, and Diesel operation show results too close and reveal a number of debatable factors that can swing the answer one way or another.

2. Present a-c and d-c systems, after years of operation and experience, still have problems showing up that increase the over-all cost of electrification and its operation.

3. The paper under discussion develops a comparison of costs based upon two hypothetical untried systems. The higher a-c and d-c voltages used and distribution layouts assumed based upon these voltages give rise to the following problems, the cost of which might make the proposed electrification unattractive:

a. The 30-mile spacing of autotransformer substations and the 15-mile spacing of d-c tie stations offer selective relaying problems with only theoretical solutions now available.

b. The 30-mile and perhaps 15-mile sections proposed, when out of service, will tie up a large section of railroad and may stop two or more trains for lack of power.

c. The 24,000-volt contact system will offer serious clearance problems in restricted overhead areas such as tunnels, overhead bridges, stations, and so forth. This may require expensive track lowering or other costly solutions.

d. Mercury-arc rectifiers for 6,000-volt traction service are not available now, and may not be available for years to come. Before they could be placed in service in the future, a considerable amount of development and experimentation will be required.

e. The loss of a d-c substation would result in a section of 120 miles between supply points, which even with all tie circuit breakers in service, will give seriously low voltage at the midpoint.

f. The assumption that for the d-c system, "phase shifters for basic wave-shape correction will presumably meet all except the most unusual requirements of inductive co-ordination" is questionable and unproved. It is more likely with the railroad type of rapidly fluctuating and moving loads that further expensive measures of mitigation will be required.

g. New locomotives required for the higher voltages would be more costly as they would be a new development.

h. Extensions to existing railroad electrifications at the higher voltages would create an expensive problem of adapting present motive power to operate from two or more voltages.

i. Proposed voltage systems would throw farther into the future the standardization, and hence the lowering of prices, of electric locomotives and apparatus for substations.

In view of the foregoing, conclusion No. 7 on page 8 of the author's paper that "Higher feeder and trolley voltages may produce further savings where the use of such voltages is indicated" is highly questionable.

D. R. MacLeod (General Electric Company, Erie, Pa.): In their paper on energy conversion and transmission costs, Kimball and Holm have included a 6-kv d-c system. Higher voltage d-c systems have been proposed ever since the first 3,000-volt d-c system was put in successful operation. Studies have been made of systems using voltages as high as 6-kv directly applied to the traction motors. The technical difficulties that have to be overcome are formidable. Every estimate has indicated that the increased cost of the rolling stock would more than offset any saving in energy conversion and transmission costs. Similar studies have been made of locomotives using rectifiers to transform the trolley voltage to a lower voltage for application to the traction motors. The results of these studies have likewise been discouraging. The results obtained by Kimball and Holm are further confirmation that there is no advantage in the 6-kv d-c system over other systems now in operation.

The 24-kv 25-cycle system used in this study would be capable of handling far more ton-miles than are given in the paper. The fleet concentration that is shown in Evans' paper[1] on power costs and described in Kimball and Holm's paper as the basis for designing the power supply, is, in our opinion very unrealistic. It is doubtful if the yard facilities that are available on a railroad operating a total of 13 trains per day would permit dispatching freight trains at frequent enough intervals to bunch the traffic in the manner indicated. A much better load factor would also have been obtained if a more realistic distribution of trains had been used as a basis for designing the system. The results of the study as shown in Tables II and V are apt to be misleading if they are used to compare the cost of electrifying the 330-mile route with the cost of moving the same traffic with Diesel-electric locomotives.

REFERENCE

1. POWER COSTS AND THE CONTRIBUTION OF EXISTING TRANSMISSION NETWORKS TOWARD COST REDUCTION OF POWER FOR ELECTRIFICATION OF MAIN LINE RAILROADS WITH MODERATE TRAFFIC, Llewellyn Evans. AIEE TRANSACTIONS, volume 67, 1948, pages 596–602.

J. G. Holm: The purpose of the paper was to stimulate interest in the subject and to invite discussion. No attempt was made to prove the advantages of one particular system of electrification over another. However, attention was directed to certain features of electrification, particularly the advantage of a leading power factor in the locomotive. Whenever these features were considered, they were always co-ordinated so as to result in a most favorable over-all electrification. It was hoped that this aspect of the paper would not be overlooked, and so it is gratifying to see its recognition in most of the discussion.

Since the discussions presented do not lend themselves to a common reply, they must be handled separately.

Withington very appropriately points out the advantages of interconnections between the public utilities supplying power to the railroad. His statement that "Most roads must operate service when it is offered" is of prime significance and implies that the roads must furnish service under all adverse conditions, in particular those arising from unexpected "bunching" of trains.

Withington points out that the cost of purchased 60-cycle power mentioned in the paper at from 4 to 6 mills per kilowatthour is too low, and that Evans in his paper[1] considered "more realistic" costs. Attention is called to Table II, Station C, of Evans' paper, where the cost of power is given at 4.37 mills per kilowatthour. The fixed charges of 8 per cent apply only to railroad financing, and public utility fixed charges for their part of the installation may be in the order of 10 per cent. The demand per train is measured at the point of supply and the assumed figure of 41 kilowatthours per thousand gross ton-miles (with locomotive) compares with 45 kilowatthours which is an average for four railroads. The two single-track rights-of-way are assumed close enough together to be fed from a common substation. The demand per train on the a-c system is greater than on the d-c system because of the losses in frequency changers, in transformers, and the reactive losses in the trolley-feeder circuits.

Brown goes even further than Withington in discussing the benefits from interchange of power during the periods of diversity. With his suggestion that the utilities generate the kind of power necessary for railroad business we are in complete agreement. The leading power factor in a locomotive may be obtained either with motor generators operating leading or with series motors whose power factor is sufficiently corrected. To accomplish this, some capacitors would have to be installed in the locomotive. Brown is correct in stating that their cost must be included in the estimates.

Brown, Gordon, and Curtis question the selection of a-c and d-c voltages. It is stated in the paper that the hypothetical railroad has no clearance problems, which is true of numerous railroads. In view of this, an a-c voltage of 24-kv with its advantages over 12-kv was used, and to give the d-c system comparable advantages, 6-kv direct current was selected.

Gordon and Curtis state a number of separate problems which in their opinion disqualify the use of higher voltages and distribution layouts assumed. The electrification discussed in the paper was assumed to be an initial electrification project and not an extension to an already partially electrified railroad. The problem of adapting existing motive power to a 2-voltage system is, therefore, eliminated. The locomotive standardization will be only slightly affected by the higher voltage suggested. With automatic reclosing of circuit breakers, normal outages will be reduced, so that interference with train movements will not be appreciable. All systems have sufficient copper in the trolley-feeder circuits to insure required midpoint voltages in case of loss of a substation so that train operation can be maintained under most adverse conditions. The problem of selective relaying has never been permitted to limit the fundamental design of an electrification. Carrier-current relaying is a possible solution. In so far as inductive co-ordination is concerned, it should be noted that in the proposed use of 12-phase rectifiers the problem of decreasing the harmonic voltages is very much easier than with 6-phase rectifiers from which perhaps the experience of the discussers is drawn.

Gordon and Curtis point out that a considerable amount of development will be required before the 6-kv rectifier will be on the market. Assurances have been received that when a demand for such rectifiers is evident, they will be supplied. In the paper ample provision for the development costs of 6-kv rectifiers has been made.

MacLeod mentions "formidable" difficulties to be overcome in the development of the 6-kv rectifier, so that the cost will more than cancel savings in the power supply system. MacLeod's opinion is that of one person in one company and his statement, to be accepted, must be supported by figures. It is hard to believe that the difficulties are so "formidable" that they will not be overcome without upsetting the over-all economic situation which definitely points to advantages of higher d-c voltages. On the other hand, there is no fundamental reason why two 3-kv rectifiers could not be connected in series, to give the desired 6,000 volts.

MacLeod and Martin criticize the train fleet concentration, calling it "unrealistic" and "disturbing." To assume that the "bunching" of trains was considered a normal operation is wrong. However, when normal train dispatching is assumed, provision must be made for emergency operation, during which the "bunching" of trains occurs due to unpredictable factors. Agreement with the degree of "bunching" assumed is not necessary, although it was based on the experience of eastern railroads, but not to allow for any "bunching" is to ignore the exigencies of railroad operation. Even though this may be condoned by some western road, it is not generally accepted practice. It is significant that none of the railroad operating men commenting on the paper objected to the assumed "bunching" of trains. Similarly, dispatching trains to suit the power load demand is not generally practiced and "not popular with most railroad managements," quoting from Withington's discussion.

MacLeod and Martin say that the road can handle a traffic larger than given in the paper. No statement to the contrary was made. Traffic designated as 157 per cent does not signify that the system is overloaded by 57 per cent. The two levels of traffic called 100 and 157 per cent might just as well have been called 63.5 and 100 per cent. Martin based all of his statements on the smaller traffic and simply ignored the larger traffic, despite the statement that at a traffic even greater than the 157 per cent figure the costs will become smaller.

In view of the foregoing, Martin's statement that for the 100 per cent traffic a total substation capacity slightly over 25 per cent of that described will suffice, cannot be taken seriously. With normal dispatching and accidental "bunching" of freight trains as assumed in the paper for the two traffics, the train sheet shows that the peak demand at each main substation is about 50,000 kw for 100 per cent traffic and 75,000 kw for 157

per cent traffic. This compares with the 60,000 kw which was assumed installed at each substation for the 157 per cent traffic. During the most adverse conditions of "bunching," the load factor is about 57 per cent. Allowing for some "bunching," the average load factor is somewhere between this figure and the 22 per cent obtained with perfect train operation after normal dispatching. An analysis of Martin's figure of $12,000,000, at current prices, indicates that his costs, reduced to a unit basis, are about 75 per cent of the corresponding 1939 costs used in the paper. Just as Martin is firmly convinced that he can electrify the assumed railroad for $12,000,000, so are we certain that his estimate is substantially inadequate. In his paper of 1946[2] Martin erred still more on the side of underestimating costs by giving a $10,000,000 figure for the electrification of a 400-mile railroad.

It is impossible to check the stated value of motive power Martin has determined to be necessary for 100 per cent traffic. It is to be understood that the authors guarded against presenting figures that are too "conservative" and tend "to handicap electrification chances." The intent of the paper was to give figures of electrification costs that are generally realistic rather than wishfully low.

Several speakers discussed dieselization. The paper made no attempt to compare electrification with dieselization. If railroad management would listen to the Diesel application engineer's "insistence" on better utilization of motive power, the same management would also listen to the many savings possible with electrification. These savings were only slightly considered in the paper. It may be stated that while today it is easier to acquire a Diesel locomotive than to furnish the capital required for electrification at present costs, possibly in the near future money, fuel and market conditions may change. With the cheaper operation of electric locomotives, this may place all the advantages on the side of electrification.

In conclusion, we wish to thank the discussers for their contributions.

Comparative Operating Results of Steam, Diesel-Electric, and Electric Motive Power on the Great Northern Railway Electrification

JOSEPH F. N. GAYNOR
NONMEMBER AIEE

Synopsis: The 75-mile single-phase 11-kv electrification of the Cascade Mountain division of the Great Northern is described briefly and the comparative performance of steam and electric locomotives is given, indicating the ability of the electric locomotive to handle 6 times the number of ton miles per hour formerly handled by steam locomotives. Mixed operation, using steam, Diesel-electric, and electric locomotives in the same trains, during the war, is described, and comparative costs of operation and maintenance for each type of motive power are given. The superior advantages of the motor-generator type of electric locomotive are set forth. Further extensions of this electrification are shown to depend on cheaper electric power costs, without restrictive demand rates. The future of electrification, in general, is shown to be closely associated with standardization of system by manufacturers, and the possible coordination of motor-generator type locomotive apparatus and equipment with that of other generator type motive power.

THE CASCADE MOUNTAIN DIVISION of the Great Northern Railway originally crossed the mountains by switchback. Later, a 3-mile tunnel was driven through the mountains between Tye, Wash., on the west side, ascending eastbound on a 1.7 per cent grade to Old Cascade on the east side to the 4,100 foot summit. Operation was by steam locomotives until 1909, when the tunnel was electrified, with 3-phase 25-cycle 6,600-volt alternating current on the double overhead contact system. The 3-phase system was selected on this pioneer electrification to obtain the required high torque characteristics of the induction motors used in the locomotives. By operating two units in multiple, with motors connected in series or concatenation, the heaviest freight trains of that period, together with their steam engines, were hauled through the tunnel at $7^1/_2$ miles per hour. This original tunnel electrification operated successfully from 1909 to 1927.[1]

The success of this 3-mile tunnel electrification turned the attention of the railroad to the benefits of electrifying its entire mountain district, between Skykomish on the west side at the foot of the 2.2 per cent grade, to Wenatchee on the east side, for a distance of 73 miles, via the new 8-mile Cascade Tunnel between Scenic on the west, and Berne, the new summit at 2,800 foot elevation on the east side.

The single-phase 25-cycle 11-kv system was selected for this new electrification, and while the new tunnel construction was in progress, the old line from Skykomish to Tye through the original 3-mile tunnel to Old Cascade, about 25 miles, was equipped for single-phase operation at 11 kv. Motor-generator type electric locomotives were selected for the single-phase electrification because of their desirable characteristics of greater capacity for handling at higher speeds any tonnage decided upon. The 25-mile section over the old line was abandoned when service was inaugurated over the 73-mile new line through the 8-mile tunnel in January 1929.[2]

During the operation of the old line with single-phase motor-generator locomotives, the advantages of electrification immediately became apparent. Steam hauled freight trains of 2,500 tons required five hours to cover the 25-mile section on 2.2 per cent grades. Three Mallet type locomotives per train were used; water stops had to be made on the ascending grade, while on the descending grades, stops had to be made to cool wheels and to inspect train for dragging brake beams, cracked wheels and so forth. Electric operation on the same section was with 3,000 ton trains, 2 electric locomotives, and running time of $1^1/_2$ hours on the ascending grades. The run on the descending grades, in regeneration, was nonstop in $1^1/_4$ hours.

The comparative performance of steam and electric motive power for this mountain service, in train ton miles per locomotive hour was as follows:

$$\text{Steam} = \frac{2{,}500 \text{ tons} \times 25 \text{ miles}}{3 \text{ locomotives} \times 5 \text{ hours}} = 4{,}150 \text{ ton miles per locomotive hour}$$

$$\text{Electric} = \frac{3{,}000 \text{ tons} \times 25 \text{ miles}}{2 \text{ electric locomotives} \times 1^1/_2 \text{ hours}} = 25{,}000 \text{ ton miles per locomotive hour}$$

giving a performance ratio between electric and steam of 25,000/4,150 or 6 to 1 in favor of electric operation on motive power performance alone. As to crew cost, electric trains had but one helper crew and one pilot conductor, while steam trains required 2 helper crews and 2 pilot conductors.

The running time for steam trains between Skykomish and Wenatchee required never less than 15 to 16 hours for this 73-mile run. This entailed not only a large amount of crew overtime, but extra crew cost as well, for relieving crews on the road in compliance with the 16 hour Federal service law. The electric trains covered this distance in 4 to 5 hours, maximum, making a very substantial saving in crew cost. After electrification, train tonnages were increased in

Paper 48-36, recommended by the AIEE land transportation committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26-30, 1948. Manuscript submitted November 11, 1947; made available for printing December 18, 1947.

JOSEPH F. N. GAYNOR is superintendent, electric operations, Great Northern Railway, Wenatchee, Wash.

successive steps up to 5,250 tons with no loss in running time. This was accomplished by multiple unit operation of 2 and 3 electric cabs so that one road crew and one helper crew could handle the maximum tonnage. It was demonstrated by numerous road tests on the 2.2 per cent grade that the motor generator type locomotives could easily handle 6,000 ton trains, this limit being determined by passing siding capacity rather than locomotive tractive effort. But for this limitation, a maximum tonnage of 7,500 could be handled.

The proper location of helper locomotives is an important factor in operating such heavy tonnage trains on grades as heavy as 2.2 per cent. Experience on this electrification indicates that 3,000 tons, trailing, behind the "swing" or middle helper, is about the maximum allowable, the balance of the tractive effort of these locomotive units being utilized to push up to 1,500 tons ahead. Head end power concentrations up to 10,000 horsepower are used successfully in such service. Maximum total horsepower per train is from 17,000 to 20,000 horsepower at rail, with continuous tractive efforts of 315,000 to 408,000 pounds, average, and up to 471,000 pounds when required for maximum tonnage. With the swing helper system, the limitations in tonnage are the length of passing tracks, and the capacity of the electric power supply, rather than the strength of drawbars. The trailing continuous tractive effort is limited to about 225,000 pounds, maximum.

The motor-generator type is the only locomotive having the necessary characteristics to move such tonnage up hill, and to hold the same by regeneration on down grade at any speed from a slow walk to the maximum capacity speed of the locomotive. Electrification alone made this type of operation and performance possible; and 20 years of satisfactory operation has proved its reliability.

The profile of the Great Northern Electrification District starting eastward at Skykomish, Wash., ascends for 12.8 miles on a compensated 2.2 per cent grade to the west portal of the 8-mile tunnel at Scenic. The tunnel grade is 1.56 per cent for 8 miles ascending to Berne, the east portal and also the summit. From Berne to Merritt is a 2.2 per cent descending grade for 7 miles, then 7 miles of rolling profile of 0.3 per cent to Winton, where the new Chumstick Cutoff line descends on a 1.6 per cent grade to Peshastin for 16.5 miles. From Peshastin to Cashmere is 8 miles of 1 per cent grade descending, changing to 0.5 per cent descending for 11 miles to Wenatchee, Wash. The eastern terminal and electric shops are located at Appleyard, 2 miles east of Wenatchee. The maximum curvature is 10 degrees. The average running time of electric freight trains over the electrified district is $3^1/_2$ hours, including one inspection stop to look over the train.

Table I. Great Northern Railway Electrification Motor-Generator Locomotive Characteristics

	Westinghouse Electric and Manufacturing Company	General Electric Company	General Electric Company
Great Northern Classification	*Z 1*	*Y 1*	*W 1*
Purchased new	1926	1927	1947
Total weight per cab or unit—pounds	360,000	518,250	720,000
Weight on drivers—inches	275,000	414,000	720,000
Wheel arrangement	1-D-1	1-C + C-1	B-D + D-B
Diameter drivers—inches	56	55	42
Diameter truck wheels—inches	36	36	42
Gear ratio	18/91	21/82	17–70
Length over cab	43 ft. 0 in.	63 ft. 0 in.	97 ft. 8 in.
Length between couplers	47 ft. 0 in.	74 ft. 0 in.	101 ft. 0 in.
Rigid wheel base	16 ft. 9 in.	15 ft. 4 in.	16 ft. 9 in.
Total wheel base	31 ft. 5 in.	58 ft. 8 in.	85 ft. 9 in.
Multiple-unit operation—number of units	2 and 3	1, 2, 3	1, 2
Trolley voltage—kv	11	11	11
Synchronized motor voltage	1,250	2,500	1,350
D-c main generator voltage	600	750	450/700
Motor-generator Set rpm	750	750	750
Tractive Effort lbs continuous	45,000	61,000	122,000
Tractive Effort lbs hourly	57,000	67,200	136,000
Tractive Effort lbs starting at 25 per cent adhesion*	68,000	103,000	180,000
Continuous speed—miles per hour	15.5	18.6	15.75
Maximum speed—miles per hour	45	55	67.5
Continuous rail horsepower	1,860	3,000	5,150
Continuous tonnage per unit on 2.2 per cent grade	750	1,000	2,000
Number of single units	10	8	2

* Electrical capacity good up to 50 per cent adhesion.

The reliability of the 11-kv inclined catenary contact system and the twin circuit 44-kv single-phase transmission lines on butt-treated cedar poles has been close to 100 per cent. Although slides and forest fires have caused delays, the service has never been interrupted by electric power failures.

The electric motive power of the Great Northern consists of 20 motor-generator type locomotives. Their classification and characteristics are shown in Table I. From this table it will be seen that the trend is toward higher powered single unit electric locomotives, capable of developing the full rated rail horsepower over the entire speed range. The Great Northern class *W-1* is the largest single cab locomotive in the world at the present time.

Mountain railroading demands large concentrations of rail horsepower and tractive effort. The basis of all performance is running adhesion continuously obtainable regardless of type of motive power, especially in bad weather. Road tests made during the past 20 years on the heavy grades and curves of the Great Northern electrification have definitely established that the best average running adhesion obtainable on good dry rails is 18 to 20 per cent, regardless of type of motive power. The all-weather average is 15 per cent. Starting adhesion with sand is between 25 and 40 per cent.

Locomotives having permanently parallel-connected electric traction motors give the best performance from an adhesion standpoint, since their driving wheels tend to creep rather than spin when adhesion is lost. Those having series-parallel connected motors have a tendency to spin down to a progressive stall under bad rail conditions, unless a light application of driver brakes is made to arrest spinning drivers and equalize the torque on all axles.

Just prior to the war, in anticipation of an electric motive power shortage, the adhesion characteristics of all three types of motive power—electric, steam Mallet type *R 1*, and 5,400 horsepower Diesel-electric were carefully determined by tests for mixed power operation. During the war, all three types were successfully used in the same train, as routine operation. Mallet pushers, cut in ahead of the caboose, handled 1,500 tons at 15 miles per hour up 2.2 per cent grades; the 5,400 horsepower 4-unit Diesel-electrics cut into the train near the middle handled 2,000 tons; while 2 or 3 units of electric locomotives on the head end handled 2,000 to 3,000 tons. Thus, trains of any desired tonnage, up to the limits set by the length of passing sidings, were successfully handled. The Diesels were operated through the 8-mile tunnel as helper engines, handling their full rated tonnage,

with electric engines on the head end.

In making the tests to determine the hauling capacity of the steam and Diesel-electric locomotives, the motor generator electric locomotives were used, regenerating, as a dynamometer—a role for which this type of locomotive is ideally adapted.

Having established the tractive effort, rail horsepower ratings, and tonnage at various speeds on the 2.2 per cent grade for each type and any combination of types of motive power, the train dispatcher could figure accurately the progress trains would make over the mountain division. The rail-horsepower found for the various types of power are shown in Table II.

Interesting figures on the gross ton miles per unit of fuel, and gross ton miles per dollar were obtained on the 2.2 per cent grade for all three types of power. Gross ton miles include the locomotives shown in Table III.

As steam helper engines were used only on the 2.2 per cent grades, and Diesel helpers were used through the entire electrified zone, the foregoing comparisons were obtained on the 2.2 per cent grade sections where all three types were working together in the same train.

The comparative operation and maintenance cost of the steam, Diesel-electric, and electric locomotives, based on figures obtained during 1941 to 1946 inclusive, in cents per mile are shown in Table IV.

The lubrication cost on the new 5,000 horsepower electrics (*W 1*) equipped with roller bearings throughout, is about 32 cents per 1,000 miles. From the foregoing costs, the electric operation speaks for itself, regardless of high power rates and heavy repairs after 15 to 20 years of continuous service.

From these figures the question of further electrification is seen to be a matter of first investment and power cost. Although the electric locomotive leads the field in performance, relatively low maintenance cost over long periods of time, and has the greatest possibilities of high rail horsepower per unit of weight and size, its first cost is relatively high when those of its contact and power transmission systems are added. Even though the efficiency, flexibility, availability, and utilization possibilities, along with the moderate maintenance cost all tend to offset the high investment cost, over a period of years, the high cost of electric power based on restrictive demand rates and ridiculous time periods in figuring peak demands is a continuing adverse factor, and causes a reduction in utilization, to control the peak demands.

Obviously, the advent of the Diesel, the fuel costs of which are not affected by such artificial and adverse economic restrictions, has changed the picture. They do a good job of railroading, and still can take a large increase in fuel cost before they are reduced to the same gross ton miles per dollar as the electric, based on the 8.5 to 10 mill power rate prevailing on this electrification since 1927.

The effect of electric power cost on future electrification extensions of the Great Northern Railway electrification has been thoroughly studied by the electrical operations and engineering departments of the ralroad, as well as other interested parties. Three proposed extensions have been worked out:

(a). 25 miles west from Skykomish to Gold Bar, at the foot of grades.

(b). 85 miles west from Skykomish to Seattle.

(c). 179 miles east from Wenatchee to Spokane.

A study of the return on investment in each case showed up very favorable, provided electric power could be purchased at 4 or 5 mills per kilowatthour with no restrictive demand charge. With the present power rates, the only extension likely, if any, would be (*a*), the 25 mile section of 1 per cent grade between Skykomish and Gold Bar.

A few years back, when small power companies with limited generating capacity were forced to write restrictive demand charges into contracts to protect themselves and their other customers from large customers taking more than their share of demand, such demand rates may have been necessary. Today, some railway electrical engineers do not agree that these out-of-date, restrictive demand rates and their methods of clocking should apply to modern operations in the midst of the North West hydroelectric power belt, with the Columbia River power dams on the east side of the Cascades furnishing their mighty loads, and the big dams on the west side, all tied into a huge network. So long as those restrictive demand rates apply, electrifications will be few and far between. Meanwhile, competitive forms of motive power will turn revenue to the coal and oil companies that otherwise could and should go for electric power if the rates were more equitable.

In a recent report of the Bonneville Power Administration, T. M. C. Martin gives data on prevailing power rates for all the major railway electrifications in the United States together with data on demand, energy consumption, load and diversity factors. These data indicate that the total demands are surprisingly small compared with the total connected loads, due to greater diversity as more mileage is included.

The motor-generator type electric locomotive has all-around desirable heavy traction characteristics and readily fits into the electrification picture. Power factor can be controlled within any desired limits. Power demand is rigidly controlled by means of train orders, limiting the synchronous amperes to any desired value, thus permitting full tonnage to be hauled on any grade at speeds proportional to the amount of power dispatched.

In regeneration, the motor-generator locomotive is superior to all other types in performance. About 40 per cent more tonnage per unit can be handled in regeneration service than can be handled continuously in hauling service up the same grade. Advantage is taken of this characteristic on the Great Northern by increasing train speeds in regeneration to the safe limits for track up to limits of substation capacity. This type of operation reduces the annual power cost by about 25 per cent, in addition to the intangible, but real savings on draft

Table II

	Rail Horsepower
5,400 Diesel	4,800
Steam Mallet *R 1* type	4,500 at 15–45 miles per hour
Electric locomotives *Y 1* (General Electric)	3,000 over speed range
Electric locomotives *Z 1* (Westinghouse Electric)	2,000 over speed range

Table III

			Gross Ton-Miles per Dollar
Steam	18.6	Gross ton-miles per gallon bunker "C" at $0.035 per gal.	= 530
Diesel	90.0	Gross ton-miles per gallon Diesel oil at $0.070 per gal.	= 1,285
Electric	6.2	Gross ton-miles per kwhr at substation at $0.0085 kwhr.	= 730

Table IV

	Steam *R 1*	5,400 hp Diesel	Electric
Fuel	59.53	40.36	35.00
Lubrication	2.02	6.20	.67
Engine house expense	7.71	9.93	4.46
Supplies	.46	.75	.38
Total operation	69.72	57.24	40.51
Repairs	41.82	20.26	17.83*
Total operation and maintenance—cents per mile	111.54	77.50	58.34

* Electric repair costs include rewinding of all main generators of 10 Westinghouse Electric and 8 General Electric and 2 spares.

gears, wheel, brake shoes and brake rigging. As an example, an electric motor-generator locomotive of the General Electric (*Y 1*) type capable of hauling 1,000 tons up a 2.2 per cent grade at 18 miles per hour, will hold the same train down a 2.2 per cent grade at 25 miles per hour, or could hold a 1,400 ton train down the same grade at 18 miles per hour. The power pumped back into the power system amounts to 25 per cent of the power purchased to pull that train up to the summit of the mountain from either end of the electrification. The recent purchase of the two latest engines of this type, which are the largest single unit locomotives yet built, confirm the satisfactory performance of the motor-generator locomotive in this service for the past 20 years.

The trend of the latest motive power design is toward the generator type, whether its prime mover be steam or gas turbine, Diesel, or synchronous motor. This would seem to be an opportune time for the various manufacturing companies to get together before further development of as many models as there are companies, all different and noninterchangeable. Some railroads are already operating large numbers of steam, electric, and Diesel-electric motive power. If as many parts as possible could be standardized, a railroad thinking of operating electric locomotives in the mountains, Diesels or gas-turbine locomotives across the plains or through the deserts, could carry one type of electric traction motor to fit all three, one wheel assembly common to all, perhaps a line of generators used singly or in multiple to fit any type of prime drive, with control and battery details enough alike so that one size of battery tray could be applied to all locomotives. Such a program would ultimately reduce the cost of all types of motive power. Any desired rail horsepower could be obtained by different make-up of wheel arrangement in power trucks, giving each railroad the chance to select the most suitable type required. Railway stores and manufacturers' service shops could reduce their stocks as one system could help any other one in an emergency. This would have meant a great deal during the war. Electrical engineers have been accused of being biased in favor of electrification. Since horsepower is all that counts in motive power, and since more horsepower can be built into electric locomotives than in any other type of motive power, it is natural to favor the system which provides the best tool, but only if it can be obtained unhampered by high first cost, and operated unhampered by high electric power costs.

The large investment and mileage existing on the Pennsylvania Railroad, New York, New Haven and Hartford, Norfolk and Western, Virginian, Reading, and Great Northern in 11-kv 25-cycle single-phase a-c electrification would seem to warrant consideration of this system as a standard. The motor-generator type locomotive seems to warrant consideration as a standard type locomotive. If such standardization for electric operation could be agreed upon by the manufacturers, and if this could be followed by a rational standardization of parts for other types of locomotives with electric drive, then electrification will again take its place and lead the field, if not shackled by high power costs.

Discussion

T. F. Perkinson (General Electric Company, Erie, Pa.): The comparative maintenance costs given in Gaynor's paper are liable to be misleading without some explanation as to what is covered by the figures.

The steam and electric locomotives concerned are 15 to 20 years old, whereas the Diesel-electrics are not more than five years old—their average age is probably less than five years for the period 1941 to 1946. It is noted that the electric costs include the rewinding of all of the main generators. Undoubtedly if the Diesels were as old as these electrics, their main generators would have been rewound at least once and possibly twice.

The writer has seen maintenance figures for a fleet of some dozen 5,400-horsepower Diesel-electrics operated in a western mountain service comparable to that of the Great Northern, wherein the cumulative maintenance costs per mile had reached 36 cents for the years 1942 to 1946 and were still rising with age. Currently the oldest locomotives in this fleet are costing in the neighborhood of 55 cents per mile for maintenance. Monthly mileages average in the neighborhood of 10,000 per 5,400-horsepower locomotive.

It is assumed that the operating costs given are per locomotive mile. If this be the case, a more meaningful comparison would have been on the basis of a thousand gross ton-miles trailing tonnage since the rail horsepower ratings (and tonnage ratings) of the electrics are considerably less than for either the steam or Diesel-electric locomotives.

Erroneous conclusions are liable to be drawn when comparing "bare" operating costs for motive-power types as different as are the three involved in the Gaynor paper. In comparing Diesel-electric and straight-electric costs it should be borne in mind that the former generates its own power, while the latter requires transmission, conversion and distribution means for energy procurement after the power is delivered to the railroad. A fair comparison of motive-power costs should assess the electric with a proportionate share of the costs of operation and maintenance of these auxiliary facilities.

The comparison of different types of motive-power systems should include not only the operating costs of the motive-power units themselves, but also the costs of the facilities, materials, and labor, peculiar to each type of power and the cost of owning the plant as a whole, if the comparisons are to be meaningful.

H. F. Brown (New York, New Haven and Hartford Railroad, New Haven, Conn.): The author's paper is an interesting addition to the previous Institute papers on the Great Northern electrification. It is one of the few papers which have actually set forth steam, electric, and Diesel-electric motive power operating costs, as well as other comparative performance. The Great Northern is one of the pioneer electrifications of the United States, and any operating data coming from this railroad is worthy of careful attention.

It is noted that comparative fuel costs were obtained on the 2.2 per cent grade for all three types of power, as follows:

Steam	530 gross ton-miles per dollar
Diesel	1,235 gross ton-miles per dollar
Electric	730 gross ton-miles per dollar

This indicates electric power consumption at the rate of 162 kilowatt-hours per thousand gross ton-miles, which is about right for the type of "elevator service" performed. However, a large percentage of this power is

presumably returned to the power supply system on the down grade through regeneration. Since the other two forms of motive power do not have this truly economic feature, should not the electric operation be credited with the power returned, for a more accurate comparison? It is mentioned elsewhere in this paper that at least 25 per cent of the entire power used on the electrified run is returned to the supply through regeneration. Using only this proportion on the grade (actually, every bit of the power regenerated should be credited to the grade, and not to the whole run) the electric power cost of $0.0085 per kilowatt-hour would be reduced by 25 per cent, or to $0.0064 per kilowatt-hour, thus making the electric gross ton-miles per dollar about 930 instead of 730, as given.

The comparative costs of operation in cents per locomotive-mile would be more readily comparable if all were on a gross ton-mile, or a rail-horsepower basis. It is not clear whether the electric locomotive costs given are per unit cab, or for the normal units operated together, as in the evident case of the Diesel-electric. If per unit cab, it is obvious that an average of 2 units must be taken to equal the rail-horsepower of the Diesel-electric, and it is possible that the costs shown for electric locomotives should be multiplied by 2 for true comparison, which would make them in general, greater than the steam locomotive costs, which does not seem possible. Possibly Gaynor will be willing to be a little more specific on this point. It is to be noted, further, that electric locomotives 20 years old, with major repairs, are compared with the repairs to Diesels which are presumably not more than three years old, which, again, is not exactly equitable.

Also for over-all comparison of costs, the line maintenance costs should be included in some way with the other costs of electric operation. An interesting fact is noted that the fuel costs of both steam and Diesel-electric operation is about 53 per cent of the total operating and maintenance costs shown, while for the electric it is about 60 per cent.

Although Gaynor states that Diesel "fuel costs . . . are not affected by such artificial and adverse economic restrictions" as electric power costs, with their "demand" charges, it is a fact that electric power costs have, in general been decreasing over the years, in spite of increases in the cost of fuels. Whether that trend will continue remains to be seen. It is not likely, however, that oil will get any cheaper, and every indication today seems to point to more "artificial and adverse economic restrictions" in the cost of that fuel than any other now in use.

Gaynor has a point to be carefully considered in his plea for standardization of motors and other electric parts; on the other hand, motor-generator locomotives show up the best on mountain grade electrifications, and are not so economic as to performance and first cost on electrifications like the New Haven or the Pennsylvania. Further, it is not outside the realm of possibilities that the electric equipment on Diesel-electric locomotives may be alternating current before many years.

Joseph F. N. Gaynor: The per locomotive mile cost comparisons as used in the paper are standard yard stick here, where all of the other data for each type power is also known in terms of thousand gross ton-miles trailing for each. The paper was mainly one to show the superior performance of motor-generator locomotives, even when operating under restrictive power contract, against other types of motive power on maximum gradients.

A 230-Kv 3-Cycle Oil Circuit Breaker for Extra-Heavy Arc Rupturing Duty

W. M. LEEDS
MEMBER AIEE

G. B. CUSHING
ASSOCIATE AEE

Synopsis: As the ultimate generating capacity of Grand Coulee Dam is approached, designers of high voltage circuit-interrupting devices are challenged to produce circuit breakers capable of interrupting faults far in excess of the present maximum standard rating of 3,500,000 kva. An oil circuit breaker designed for extra-heavy arc rupturing duty is described in this paper. Results of varification tests made in the laboratory are compared with those obtained on subsequent field tests at Grand Coulee Dam. The close correlation of circuit breaker performance in the field and laboratory confirms the accuracy of the laboratory method of testing. With successful correlation up to 7,500,000 kva and laboratory tests simulating still higher rupturing duty, there is now a sound basis for design of oil circuit breakers with a rated interrupting capacity up to 10,000,000 kva.

THE highest rated interrupting capacity of any 230-kv circuit breaker now installed is 3,500,000 kva. At a number of locations in the United States and in Canada short-circuit interrupting ratings of 5,000,000 kva will be required shortly. However, the tremendous power concentration at Grand Coulee Dam involved in an ultimate installation of 18 generators of 108,000 kva and 12 synchronous pump motors of 65,000 horsepower each results in fantastic short-circuit values approaching 15,000,000 kva if all machines are connected together on a solid bus and all of the transformer neutrals are solidly grounded. This includes feedback from the Bonneville Power System with the ultimate number of transmission lines connected. Even with sufficient reactance in the transformer neutrals to limit single-phase short-circuit currents to the 3-phase values, some additional limiting impedance between bus sections is required to keep the maximum short circuits below 10,000,000 kva unless pumps and associated generators are isolated from the system. This paper describes the design features of an oil circuit breaker suitable for interrupting duty between 7,500,000 and 10,000,000 kva with 3-cycle interrupting time.

Among the features required of such a circuit breaker in addition to high-speed arc rupture and tremendous short-circuit interrupting ability should be included provision for operation on a 20-cycle reclosing duty cycle so as to improve the stability of the large interconnected system. Although circuit breakers for 230 kv are normally rated 800 amperes, a continuous current rating of 1,000 amperes is required for this application, since calculations show that currents of between 900 and 1,000 amperes may have to be carried through the line circuit breakers during emergency conditions when a line is out of service.

Theory and experience in connection with the de-energizing of long high-voltage transmission lines have shown the possibility of switching-surge voltages of several times normal unless the charging current is extinguished without more than one restrike defined as an arc reignition after a current zero pause of 1/4 cycle or more. Laboratory and field tests on the type of circuit breaker decribed in this paper have shown the ability to interrupt line charging current promptly without the complication of large voltage-controlling resistors.

Steel-Tank Circuit Breaker Design

Just a few years ago 230-kv circuit breakers with interrupting ratings of 2,500,000 kva were built in steel tanks 108 inches in diameter. However, the development of the multiflow type of circuit interrupter[1] has made possible the design of a line of oil circuit breakers with a very substantial reduction in tank diameter and oil volume. Circuit breakers with full 230-kv insulation are now being built in 84 inch diameter tanks while the reduced-insulation design for use on systems with effectively-grounded neutrals are produced in 78 inch diameter tanks. Since the amount of gas generated during arc interruption is relatively small with the latest type interrupters, the clearances between live parts and ground are determined largely by the insulation tests rather than the amount of rupturing capacity. For this reason the extra-heavy arc rupturing duty circuit breaker described in this paper operates entirely satisfactorily in an 84 inch diameter tank. A section view of one pole of the circuit breaker is illustrated in Figure 1. The development of the completely-sealed oil-impregnated condenser type bushing[2] has provided rugged insulated terminals of such small diameter that they do not themselves present a limitation in the size and shape of the circuit breaker tank. Adequate space is available for as many as two current transformers on each bushing.

The mechanical closing effort applied to the interrupters by the circuit breaker lift rod is very nearly the same as in the lower interrupting capacity circuit breakers which have been operating successfully for a number of years.[3] A pneumatic mechanism with a $9^1/_2$ inch diameter piston is used to close the circuit breaker (Figure 2). The mechanism lever system is arranged so that on normal tripping the piston remains connected to the circuit breaker pull rod. This permits rapid reclosure from any point in the mechanism stroke. However, if the circuit breaker is tripped immediately following the closing operation, the pull

Paper 48-40, recommended by the AIEE switchgear committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26-30, 1948. Manuscript submitted November 7, 1947; made available for printing December 4, 1947.

W. M. LEEDS and G. B. CUSHING are with the power circuit breaker engineering department of the Westinghouse Electric Corporation, East Pittsburgh, Pa.

Tank diameter is only 84 inches compared to older 3,500,000-kva circuit breakers with 108-inch tanks

rod is disengaged from the piston so that residual air pressure will not influence the opening speed. With such a mechanism the circuit breaker is fully equipped to operate on a modern reclosing duty cycle with reclosing intervals as short as 20 cycles. The multiflow circuit type of interrupter has shown remarkable arc-extinguishing effectiveness over a wide range of voltage applications. The particular design adopted for the high capacity 230-kv circuit breaker described in this paper is illustrated in Figure 3 and in section view by Figure 4. It will be noted that two arcs are drawn substantially simultaneously, gas pressure generated in the lower break driving oil up two channels and then through pairs of inlets so as to converge on the main arc in the upper break at a number of different levels along its length. As the oil flows upward and downward through orifices in which the arc is drawn, gaseous arc products and carbonized particles are swept out of the vents interspersed between the inlets. The cooling and deionizing action of this flow builds up dielectric strength with such rapidity at a current zero that the arc does not reignite and the circuit is interrupted.

In order to speed up the opening of low currents, such as transmission-line charging currents, a spring driven oil-driving piston is provided to supplement the normal self-generated flow. The oil is introduced through a multiorifice structure in the lower or pressure break before entering the main channels to the upper break. This provides maximum interrupting effectiveness when the piston starts to function after an intentional delay to allow the contacts to open far enough so that reignition will not take place after the very first attempt to clear. On high current interruptions the piston will be held by back pressure until after arc extinction when the grid pressure falls rapidly and allows a flow of clean oil to flush out the structure.

Equal division of recovery voltage between the two interrupters in a pole unit is assured by resistor columns paralleling each stationary contact assembly. These consist of carbon-impregnated ceramic blocks assembled in a pair of fibre tubes which are mounted on either side of the contact-operating rod. (See Figure 4.) The resistance value of 400,000 ohms per interrupter is low enough to perform its voltage-dividing function adequately and yet high enough that the small residual current of only 1/6 ampere is interrupted promptly when the circuit breaker cross-arm disconnects from the fingers at the bottom of the grid.

Large size resistors of only a few thousand ohms for the purpose of limiting overvoltages due to arc restriking during the interruption of line charging current have the disadvantage of a 25 to 50 ampere residual current which requires several cycles of arcing before interruption in the disconnect gap. The provision of an oil-driving piston which prevents delayed restriking of the arc eliminates the need for such a resistor.

A considerable margin of safety in interrupting ability has been demonstrated in a 230-kv 3-cycle 3,500,000-kva circuit breaker equipped with multiflow grids by field tests carried to 4,370,000 kva. These tests were reported to the AIEE in August 1946.[4] No limitation in interrupting capacity has been found as yet to the multiflow principle, the higher capacity interrupters requiring principally detail design changes in the oil flow control and an increase in ruggedness of construction. For instance, the phenolic-resin-impregnated wood tie rods holding the grid assembly together have been increased appreciably in diameter for the interruption of currents up to 25,000 amperes. The strain on these tie rods is kept down by designing the fibre structure so that a minimum of area will be exposed to the internal pressure.

Figure 2. Pneumatic operating mechanism capable of reclosing a large oil circuit breaker within an elapsed time of 1/3 second after a short-circuit current interruption

Figure 3. Multiflow grid with shields in place designed for extra-heavy arc rupturing duty at 230 kv

Figure 4. Section through 230-kv multiflow interrupter designed for extra-heavy arc rupturing duty

Tripping of circuit breaker releases main cross arm *A* allowing spring *B* to move operating rod *C* downward and rotate levers *D* and *E* withdrawing upper contact *F* and establishing arc *G* in the interrupting chamber. Simultaneously, pin *H* swings lever *I* downward, pulling lower contact *J* away from the intermediate contact *K* to draw pressure arc *L*. Pressure from arc *L* drives oil through channels *M* to multiflow inlets *N*, deionizing arc *G* in multiorifice structure and sending arc products out vents *O*. Spring *P* pushes piston *Q* downward to provide supplementary oil flow for low current arc interruption or scavenging flow after high current interruption, driving oil through channel *R* to orifice structure *S* in lower gap and then to main flow channels *M*. Resistor *T* assures equal division of restored voltage between the two interrupters of a pole unit following interruption of the short circuit

Although the primary consideration in extending the interrupting capacity is physical strength, the momentary current that must be carried by the contacts during the initial cycles of short circuit does run into a limitation for silver-tungsten butt-type arcing tips with relatively light contact pressure and small cross-section area. The introduction of finger contacts, greatly increased contact pressures, or more massive arcing contact elements all would result in a substantial increase in accelerating effort, and in the corresponding mechanism closing force, required to maintain adequate operating speed. For a 25,000-ampere interrupting capacity corresponding to 10,000,000 kva at 230 kv, the momentary current rating is approximately 34,000 amperes. This is higher than any similar butt-type contact momentary rating, and a radical change in design might be necessary if still higher momentary current ratings were required. However, if greater concentration of power in the future should necessitate higher rupturing capacity there are many factors to suggest going to a higher voltage rating which would keep the interrupted current and momentary current values within reasonable limits. The use of copper-alloy arcing contacts one inch in diameter has been selected to provide more conductivity and greater mechanical ruggedness for the heavy duty than the former aluminum and copper contact construction. Actually the moving mass is somewhat greater, and the accelerating effort has been increased accordingly.

High Power Laboratory Tests

The interrupting ability of the described circuit breaker was investigated in the Westinghouse A-C High Power Laboratory. Here the full power of the laboratory generators was used to demonstrate the interruption of high short-circuit currents. Also, the interruption of capacitive currents comparable in magnitude to those associated with the charging of transmission lines was demonstrated using a capacitor bank to simulate the capacitance of the line.

Adequate demonstration of interrupting capacity approaching 10,000,000 kva at 230 kv requires a diversity of laboratory connections not generally utilized when verifying lower capacity circuit breakers.[5] The limit to which a single pole unit can be tested at a voltage of 132 kv, equal to the line-to-ground voltage of a 230-kv system, is about 12,000 amperes, taking advantage of maximum asymmetry in the current wave. This represents a 3-phase fault at 230 kv of 4,800,000 kva with a freely-oscillating recovery voltage rising at a maximum rate of 3,400-volts per microsecond.

When provision is made to assure equal division of recovery voltage between the two interrupters within a pole unit, each of these single interrupters when tested on half voltage at a given current may be considered to undergo duty comparable to that imposed on the two interrupters of a pole unit tested at the same current and full line-to-ground voltage. Therefore, by connecting the laboratory transformers for 66 kv, short circuit currents up to 24,000 amperes can be delivered to a single interrupter, representing a 3-phase fault at 230 kv of 9,600,000 kva. The maximum recovery voltage rate of 3,200-

volts per microsecond on one-half the pole unit corresponds to 6,400-volts per microsecond on the complete circuit breaker.

In order to confirm the ability of all of the circuit breaker pole-unit components to withstand the mechanical stresses resulting from simultaneous arcing in both interrupters, the 3-phase connection at 66 kv illustrated in Figure 5 provides higher equivalent short-circuit power than can be obtained directly on the full pole unit. It will be noted that one phase from the delta-connected transformers is brought to each terminal of the pole unit, and the grounded third phase to the pole unit cross arm through a flexible connection. By this means current is supplied to each interrupter corresponding to an 8,000,000-kva 3-phase fault on the complete circuit breaker, and with recovery voltage conditions comparable to that encountered in 230-kv service.

The single pole test circuit breaker, equipped with high-capacity multiflow interrupters, was tested under each of the three conditions just described, each test circuit adding something to the complete picture of interrupting performance. Test results are tabulated in Table I and II. Interrupting time has been plotted as a function of current in Figure 6. Uniformity in interrupting time throughout the current range is apparent. Also evident is the similarity in performance obtained using the three different laboratory connections.

Outstanding performance is demonstrated in test 18, Table I. With this operation an equivalent of 9,720,000 kva was interrupted 2.5 cycles after the trip coil was energized. Following this test a second interruption, test 19, Table I, of 9,600,000 kva was accomplished in the same interrupting time. Figure 7*a* is the oscillogram taken in conjunction with the former of these tests. Oscillograms Figure 7*b* and 7*c* pertain to test 14 and test 25, Table I, respectively which are typical records of circuit breaker performance using the 132-kv single phase and the 66-kv 3-phase laboratory test circuits.

In preparing for field tests at Grand Coulee Dam it was understood that a reclosing duty cycle with a 60-cycle time interval between interruptions was to be specified, and a number of tests were made to determine the effects of such duty on the circuit breaker performance. In general there appeared to be very little difference in interrupting performance, between the first and second interruptions. However, in the current range around 6,000 amperes under the high voltage recovery rate of the laboratory (3,200-volts per microsecond) the interrupting time of the second interruption occasionally extended beyond three cycles, due apparently to delay in building up full oil-driving pressure because of the residual gas cushion from the first interruption. Data from these tests are tabulated in Table II. The maximum equivalent kilovolt-ampere interrupted in the laboratory during a 60-cycle reclosing duty cycle is tabulated under test 7, Table II. In this test the interruption of an equivalent of 8,500,000 kva was followed by reclosing and immediate interruption of 7,200,000 kva. This is believed to be the first time that such enormous interrupting capacity has been demonstrated on a reclosing duty cycle either in the laboratory or on an operating power system. Figure 8 is the oscillogram of this test.

The ability of the interrupter to meet the conditions imposed when switching capacitive circuits has been thoroughly tested at currents of 45, 90, and 165 amperes with normal operating voltage applied across a single interrupter. Of a total of approximately 125 tests all interruptions were accomplished in less than three cycles, extinction occurring at the current zero following the initiation of forced oil flow. An extremely low probability of even a single delayed restrike was demonstrated, and in no case were voltages higher than double the peak voltage of the circuit experienced.

Field Tests at Grand Coulee Dam

While a large laboratory is a versatile tool in the development of high-power circuit breakers, because of the high interrupting capacity of the described circuit breaker, there are two service conditions which are not fully duplicated by laboratory tests and may be proved more reliably in the field. Only with the generating capacity which is available at

Grand Coulee Dam can a full pole unit be tested to an interrupting capacity of 7,500,000 kva with full line-to-ground voltage restored between one terminal and tank. Accordingly, field tests give better evidence that gas which is generated during interruption will not disrupt the dielectric strength between live parts and ground to the extent of causing flashover. Also, only under field conditions can all of the interrupters within a pole unit be tested in series at line-to-ground voltage at this high interrupting capacity. However, circuit breaker design factors are established and checked in the laboratory with sufficient accuracy to justify confidence when field testing at extended ratings.

On the other hand, it is characteristic of field tests that the rate of rise of recovery voltage on high-power short circuits is quite low because of the added capacitance of the interconnecting transmission lines and the damping effect of parallel loads. For this reason caution must be exercised in interpreting successful field tests at one location as complete verification of performance at another location where the recovery rate is appreciably higher. It is evident, therefore, that the best over-all picture of circuit breaker performance in the higher range of interrupting capacity ratings is given by the combination of laboratory tests at high recovery voltage rates up to the maximum available power and field tests at full rated capacity with the maximum available rate of rise of recovery voltage.

Although it is impractical to reproduce rigorously transmission line phenomena within the laboratory, the switching of large capacitor banks does approximate circuit breaker performance when opening line charging currents. These results in general are confirmed by transmission-line switching tests, which also add data on the actual amplitude of voltage surges due to traveling waves on the lines.[6]

A complete account of tests conducted at the Coulee Dam switchyard is presented in a companion paper.[7] Briefly two series of short-circuit tests were made on the new type *GM* circuit breaker pole unit. The first comprised 15 close-open (CO) operations, 12 of which were included in standard CO-15 second-CO duty cycles. The second series consisted of seven complete reclosing duty cycles, each with an initial fault interruption, then reclosure within an interval as long as 60 cycles and as short as 18 cycles followed by a second clearing of the short circuit. In addition there were seven tests opening an arcing fault in which the arc was not re-established even though the circuit breaker was reclosed within as short an interval as $12^1/_2$ cycles.

The extremely high interrupting capacities demonstrated are unparalleled among field tests. One test equivalent to the interruption of a 3-phase 7,500,000-kva fault was accomplished in the unusually short time of 1.85 cycles. After a pause of 15 seconds a second CO operation interrupted the equivalent of 7,340,000 kva without damage to the circuit breaker.

Among the 60-cycle reclosing tests was one interruption equivalent to 6,000,000-kva 3-phase, while the 18-cycle reclosing operations were carried up to 5,130,000 kva without the least external evidence of stress. There was no apparent difference in the arcing time for first or second interruptions, the total time from energizing the trip coil to arc extinction varying between 2.1 and 2.65 cycles for all of the higher power tests. From this data it is evident that sufficient oil is available in the grid structure to interrupt at least two heavy short circuits in rapid succession without the necessity of complete replacement of gas with fresh oil.

The interrupting time obtained in both the standard duty-cycle tests and the rapid-reclosing tests has been plotted in Figure 9 for each current interrupted. Superposed on this plot is the curve of interrupting time as a function of current determined by laboratory tests and transferred from Figure 6 with a small correction to allow for the additional time to part contacts required by the pole unit tested in the field. It should be noted that the average interrupting time for the points plotted from field tests data is discontinuous, indicating a change in the circuit by the addition of transmission

Figure 8. Oscillogram of a reclosing duty cycle test on a laboratory circuit approximating the current and voltage conditions of a 230-kv 3-phase fault of 8,500,000 kva

A single interrupter constituting half of a circuit breaker pole unit interrupts at 66 kv a current of 21,300 amperes, recloses the circuit in one second, and promptly interrupts the re-established current of 18,150 amperes

Figure 9 (right). Interrupting performance of the 230-kv circuit breaker tested at the Grand Coulee Dam

Dashed line, representing average interrupting time is discontinuous where transmission lines of the Bonneville Power System were connected to obtain additional short circuit power, reducing the voltage recovery rate. The bus voltage was lowered from 241.5 kv to 238 kv (respectively 140 kv and 138 kv to ground). Solid line represents average interrupting time from the laboratory data of Figure 6

lines which resulted in a reduction in the recovery voltage rate from approximately 1,200 to only 250 volts per microsecond. Three of the interruptions at 1,200 amperes showed somewhat longer interrupting time than average, two of these having followed as many as 10 earlier operations interrupting in excess of 4,000,000 kva.

Field data are closely correlated with results obtained in the laboratory. For instance, in the current range below 3,000 amperes where an isolated bus energized by one or two generators supplied the fault and provided a high recovery voltage rate, the interrupting times for laboratory and field tests were almost identical. A downward trend in interrupting time as the current is increased is attributed primarily to the corresponding decrease in recovery voltage rate, which is typical of field conditions where higher currents are obtained by interconnection to more remote sources of power. Laboratory circuits on the contrary provide maximum recovery voltage rate on the maximum current tests where the inductive reactance is a minimum and the capacitance to ground relatively unchanged. The slightly shorter average interrupting time shown on the highest power tests in the field therefore was to be expected. In general, the close agreement of laboratory and field results appears to justify in a very gratifying way the method used for laboratory verification of interrupting capacity.

Conclusions

A comprehensive investigation involving both laboratory and field tests has demonstrated that the multiflow principle of arc interruption can be utilized on high-voltage applications considerably beyond existing circuit breaker ratings. The design described in this paper has been verified by direct field test up to an interrupting capacity of 7,500,000 kva and by laboratory test to the extreme limit of the facilities, or 9,700,000 kva. Arc-rupturing performance has proven adequate on a high-speed reclosing duty cycle in which the reclosing interval was reduced to 18 cycles, approximately the minimum considered for 230-kv systems. Furthermore, the ability of the pneumatic mechanism to reclose the circuit breaker if necessary within intervals as short as 12 cycles was demonstrated.

While no limit has been reached in the interrupting capacity to which multiflow type interrupters may be adapted, the momentary current-carrying capacity of light-weight high-speed contacts imposes a practical limitation of approximately 25,000 amperes rated interrupting capacity. This corresponds to a 3-phase interrupting capacity of 10,000,000 kva at 230 kv.

Field tests on a complete pole unit of a

circuit breaker provided with means for controlling the division of voltage among the individual breaks have confirmed laboratory results with half a pole unit tested at half voltage, establishing further confidence in the laboratory practice of extending the current range of tests by testing subdivisions of a pole unit at appropriately reduced voltage.

On the basis of the extensive laboratory and field testing described in this paper, oil circuit breakers may now be built with confidence having interrupting ratings as high as 10,000,000 kva at 230 kv for either standard or reclosing operating duty.

Discussion

Robert H. Nau (University of Illinois, Urbana, Ill.): Most of the material in Leeds' and Cushing's paper has naturally been concerned with a presentation of the test results and general over-all design features of a high-power circuit breaker for 230-kv performance. They have mentioned this sizeable reduction in steel tank diameters which the multiflow deion grid has made possible.

I should like to emphasize some of the fundamental design features of this particular multiflow grid design which will indicate the evolution of thought on this type of grid and also indicate possible refinements in the future. These details have been gathered at various times in discussions with Frank Fry, a colleague of mine on the faculty at the University of Illinois.

This grid is inverted in comparison with all other types of multiflow grids, which results in advantages both in oil flow from the driving piston and in the mechanical loading of all members because all the accelerating springs for the grid are connected through short and relatively light metal members to the circuit breaker crossarm.

The orifice through which the arc is drawn is actually $^1/_4$ inch smaller in diameter than that for the existing lower kilovolt-ampere capacity circuit breakers. This reduction in orifice area helps materially in the design of the oil driving piston and was made possible through a study of the orifice area requirements for various arc currents.

While the length of the present unit has remained substantially the same as that for the existing 230-kv 3,500,000-kva interrupters, the grid diameter has actually been reduced by several inches. In other words, although the kilovolt-amperes to be interrupted has been more than doubled, the grid was actually reduced in size in its more critical diametrical dimension. This indicates the trend in modern controlled designs for high-capacity circuit breakers.

P. L. Taylor (Allis-Chalmers Manufacturing Company, Boston, Mass.): I want to compliment the authors on their work in outlining such a marked extension of the range of interrupting capacity of power circuit breakers in the transmission class.

The effect of the tripling of the range of available interrupting capacities at the higher transmission voltages upon power system design seems almost certain to be far reaching.

It is peculiarly fitting that these tests indicating the feasibility of oil circuit breakers up to 10,000,000 kva were made in 1947, the fiftieth anniversary year of the first oil circuit breaker, which was designed by Dr. Leonard Elden in 1897. That these fiftieth anniversary oil circuit breakers are pneumatically operated and that some of the earliest designs of the Elden oil circuit breaker were also pneumatically operated, is worthy of note. The comments of Rietz in a companion paper[1] with regard to oil circuit breakers seem to me to be quite significant. He has said in part

"The modern tank type circuit breaker represents a product of years of evolution that in itself bespeaks a series of improvements that ought to reflect in capacity beyond its rating."

It has been our experience also, that the oil circuit breaker has a way of coming through.

Again I want to compliment the authors on their most important contribution.

W. M. Leeds and **G. B. Cushing:** The authors appreciate very much the supplementary discussion presented by both Nau and Taylor. The confidence expressed in the high-voltage dead-tank circuit breaker designs is very heartening, confirming our judgment that this type of switchgear provides the best solution to the heavy arc rupturing capacity problem in the high voltage outdoor circuit breaker field. It is interesting to note that in spite of the availability of the porcelain-clad impulse circuit breaker for some 13 years, manufacturers of this equipment have seen fit to bring out quite recently a completely redesigned line of steel tank circuit breakers to meet the same ratings as the oil-poor apparatus. We believe that we are best meeting the needs of the electrical industry by concentrating our efforts on only one general design of high voltage oil circuit breaker. We have endeavored to combine the advantages of a stored energy arc rupturing device, not requiring large control resistors for switching line-charging currents, with the ruggedness of the steel tank structure and the moderate operating load requirements of a two-unit-per-pole self-generating oil-flow type of interrupter capable of clearing rapidly and easily short circuits of the highest power available.

Are the Overhead Distribution Costs Retarding Railroad Electrification?

L. W. BIRCH
MEMBER AIEE

Synopsis: If terminals, suburban lines, and open-pit mining developments are excepted, the electrification of heavy haulage on the North American continent has progressed rather slowly for the past 15 years. In the meantime, and particularly postwar, European countries definitely have announced their decision to make extensive additions to their electrified railroads. Similar decisions have issued from other countries. No doubt, there is a satisfactory reason for this slowing down of electrification in North America. Based on the thorough and efficient operating methods followed by the railroads of North America, it may be concluded that economics may play some part in this "slowdown." Possibly the first cost of electrification is too high; if so, how can this first cost be reduced, or be made comparable to installations involving other motive power? It cannot be said that the high first cost of electrification is entirely due to the cost of the overhead distribution system. But, it can be said that the overhead system, as a part of the electrification plant, may contribute to high costs. It is not conceded that unfavorable first costs of electrification are the deciding factor in favor of some other mode of transportation, but a reduction in the first cost of electrification certainly will place the electric locomotive in a more favorable place. This paper describes some of the new overhead equipment, also system and structure designs, that have been developed in very recent years. The paper also calls attention to the many methods of cost reduction possible with many of these designs, also obtainable by following modern erection practices and by reducing engineering costs.

IF overhead distribution costs are retarding railroad electrification, what can be done to reduce these costs? Transportation is vital to our very existence. Without good transportation we would be struggling along in isolated communities, with few of the necessities of life and with none of the luxuries. Transportation has developed man, our country, and industry. There is nothing new about this statement. But the demands on transportation are ever changing. And now our vast country developed and expanded by transportation, demands that transportation keep pace with this development. Today, it is not enough to carry a passenger from Montreal to Vancouver, or from New York to San Francisco in four days. Besides speed the passenger wants comfort, a smooth ride, and safety. The shipper emphasizes speed in his demands, because of smaller inventories, nation-wide consumption of perishables, and sudden emergencies such as produced by World War II. Any old schedule and any old equipment will not be tolerated.

Our railroads have gone a long way toward meeting these demands since the Baltimore & Ohio Railroad initiated steam service in 1828, since the Santa Fe headed west from Topeka in 1869, and since the last spike was driven on the Canadian Pacific's transcontinental route in 1885. The railroads have developed higher average speeds, have furnished the passenger with many comforts of travel, and have given the shipper better service at lower rates.

The electrification of railroads can carry on this program still further. Then why is electrification in North America progressing at a snail's pace? Possibly the question should be reversed. Why are South America, Switzerland, and Sweden electrifying? Why are Belgium, Austria, France, Spain, Africa, and India making definite plans for extensive electrification? Of course, the true answer is one of economics and the principal factors affecting the ultimate selection of motive power are the cost of fuel and the capital expenditures for locomotives and overhead equipment which is approximately one-fourth of the total cost of electrification. It is the purpose of this discussion to analyze the distribution system and suggest means for reducing its cost.

Basis for Overhead Cost Reduction

The present-day competitor of electrification is the Diesel locomotive. Although the difference in first cost of a Diesel installation and an electrification may just equal the cost of the overhead system, we cannot say that in order to justify electrification the overhead system must be obtained free of cost. If a reduction in costs is necessary to balance the first cost of electrification with that of dieselization, then all factors in the estimate must bear their proportionate decrease.

The method for determining the per cent reduction of overhead costs in this paper is based on averages of three estimates. Incidentally, one of the electrifications for which one of these estimates was made is practically finished. The three estimates include a large industrial 3,000-volt d-c project; a long wood-pole single-track 11-kv Western railroad project, and a large Eastern multiple-track project. The increase in costs of electrification over dieselization were found to be 0 per cent, 16 per cent, and 37 per cent in the order named. The per cent cost of the distribution system based on the total cost of electrification was found to be 26 per cent, 27 per cent, and 28 per cent in the order named. It was fairly well established from these last percentages that the overhead system averaged only 27 per cent of the total cost of electrification. We are interested in reducing this 27 per cent factor. Now the industrial estimate showed no savings in first cost for the Diesel, the western road

Paper 49-38, recommended by the AIEE land transportation committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26-30, 1948. Manuscript submitted November 12, 1947; made available for printing December 10, 1947.

L. W. Birch is engineer, transportation department, Ohio Brass Company, Mansfield, Ohio.

Figure 1. Work train cost always has accounted for a huge portion of the total labor cost of electrification

16 per cent, and the eastern road 37 per cent. Since we are particularly concerned with the single- and double-track electrifications, an average of these latter percentages, 18 per cent, should be satisfactory for our example. By simple mathematics it can be easily determined that this 18 per cent increase in first cost of electrification over dieselization requires a 15 per cent reduction in electrification costs—straight across the board—if first costs are to be equated. If operating costs are to be considered this drastic reduction may not be necessary to equalize costs, but for the sake of illustration this procedure will be undertaken in order to assign the 15 per cent cost reduction to the distribution system. It is not claimed that this figure is accurate for all installations, and it is not implied that other factors of cost can be adjusted by exactly the same per cent. This example is given to call attention to a possible goal for cost reduction in the overhead system. Now, let us review the recent developments in overhead design and construction and see if this amount of cost reduction is possible. If so, we may conclude that overhead distribution costs are *not*, as an individual unit, greatly retarding electrification.

Prewar Effort to Reduce Cost

Immediately following the depression and continuing until stopped by the war, several of the large electrical manufacturers aided by a representation from steel fabricators, cable manufacturers, and overhead system manufacturers, formed a committee of engineers to study overhead distribution with one primary thought in mind—to reduce costs. This work was not restricted to materials alone, but involved considerable construction study, particularly from the standpoint of off-track equipment. It was recognized by this committee that work train cost has always accounted for a huge portion of the total labor costs. Also, based on the experience of the engineers participating in this work, it became quite evident that another reason for some of the high costs of the overhead system was attributable to the many and varied distribution systems found on our various railroad electrifications that were accomplishing the same purpose. No doubt, high development costs accompanied these installations. Duplicate designs could have been chosen for most of these electrifications. Again, it was found that many steel structures had been designed "on the heavy side." In many of these cases the hand of the railroad's bridge department was recognized. There seemed to be a great variation in the choice of cables, not as serious a fault as too much steel, but representing thousands of hours of study on the part of a group of engineers.

A recent and exhaustive study of the catenary span to determine the cheapest combination of cables for a given load and a given span length included a total of 20 different spans. These involved composite cables of various sizes and capacities, also several different sizes of auxiliary and trolley wires. What was the outcome of this study? Almost nothing. Any combination would have been satisfactory from a cost viewpoint. The final choice could not be made on the basis of cost.

The committee also found a wide variation in the selection of hardware. This may not represent a big increase in overhead system costs, but somebody had to pay for development, and development charges, whether made by the railroad or the manufacturer, are readily recognizable in the totals. The committee believed that engineering costs were too high on many electrifications. One prevalent cause for high engineering costs was due to the vast amount of steel structure

Figure 3. Wood structure in Utah supporting same weight-per-foot of catenary as Nevada structure (Figure 2)

Figure 2. Steel catenary structure in Nevada (see Figure 3)

Figure 4 (left). Steel portal structure built with shapes

Figure 6. Two-track bracket on Montreal Terminals electrification

detailing by the electrification engineers. After all, the fabricator duplicates this work. He must for his own shop. Then why provide the fabricator with steel details? Just give him the ruling dimensions, limitations, and space diagrams and he will provide the finished design.

Stopping at this point would probably leave you with some conception of the possibilities of cost reduction. However, a discussion on catenary installations during the past 8 years may serve further to emphasize this subject, particularly by showing that further cost reduction is possible.

For the sake of clarity, this discussion of cost will be segregated into three main subjects. Each will be treated separately.

There is one division of overhead system costs that is familiar to all railway electrification men and this may be termed

1. *Standard costs* for want of a better name. The standard costs include direct labor and material for structures, catenary, switching equipment, track bonding, and other accessories contingent to the construction of the distribution system. Another division of costs may be placed in a second classification known as

2. *Clearances* which covers all anticipated expenditures for special designs considered necessary for signal, communication, and overhead bridge interference, also for the unusual headroom demanded by some companies. Another important item of cost may be called

3. *Psychological barriers*, a term which seems to be somewhat meaningless; however, this cost classification represents considerable money in every estimate. It deals chiefly with planning and engineering and is swollen in direct proportion to the ability of the engineer in charge to enlarge and glorify his organization.

Standard Costs

These costs include all labor and material costs for the structure, the catenary system, switching equipment, track bonds, and other contingencies that are necessary for the construction of the distribution system. They do not include the cost of office engineering, layout, inspection, signal changes, highway bridge and tunnel alterations, moving other wayside structures, and other innumerable items that would not be considered if the electrification were installed on a newly built railroad.

Structures

Although two electrified systems may be identical, the structures are apt to be different. Criticism of dissimilar structures on identical systems cannot be made until all conditions are known. Costs of material and labor, at the time of construction, greatly affect design. An electrification in Nevada during the depression was built with steel structures, 12-inch *CB* sections having been selected for the columns. Steel was cheap and labor costs were low. Later an equivalent installation in Utah was built with wood, construction costs having increased to influence this change. A similar situation is to be found in Canada. An earlier installation was built with steel while a subsequent electrification of steam-road tracks was accomplished with wood. In both examples the structures are supporting equivalent mechanical loads and maintenance costs are about the same.

Since this discussion deals chiefly with the lighter types of distribution systems, for 1- and 2-track sections rather than with the heavier types, four cost comparisons of 2-track structures may serve to illustrate the problem of structure economy. First a breakdown will be provided for two types of steel structures spaced 300 feet apart and carrying a

Figure 5. Steel cross-span structure on outside haulage of Pittsburgh Consolidation Coal Company

Figure 7. Wood cross-span construction, Canadian National Railways

Figure 8 (left). The handling cost of structures may be greatly reduced by the elimination of a certain amount of storage

Figure 9. Two-track portal structures with laced truss and columns usually cost more than structures built of shapes

catenary system of 3 pounds per foot. The cost of fabricated steel is 5 cents per pound.

	Steel Portal	Steel Cross Span
Cost of steel	$400	$250
Cost of cross-spans		65
	400	315
Labor, erecting	120	110
	520	425
Concrete footings	350	210
Guys		330
	$870	$965

The comparison shown in the foregoing tabulation was not provided for the purpose of selecting the cheapest structure. It was reproduced to show the breakdown of costs, which includes only structure items, and not any portion of the distribution system such as cables and hardware. To illustrate structure costs and to make a reasonably accurate comparison, two additional types of structures will be added, one of which is wood. Only the total costs will be given in Table I since the first tabulation has provided the breakdown.

In this table the increases in cost are progressive. The costs shown in the last line include all of the increases described in the left-hand column. Incidentally, these figures actually show the increases in labor and material for the last two years.

Returning to the two references concerning the initial building with steel and the subsequent building with wood, the comparison of costs for the portal structure and the wood cross span show that with 5 cent steel the portal is slightly cheaper than wood and with 7 cent steel, higher concrete cost, and higher labor cost, the wood pole structure is cheaper. However, if the comparisons are analyzed closely it will be observed that the differences in total cost for the steel structures are small. This would lead one to believe that the choice of steel structures is not necessarily based on first cost.

If it is agreed that the first cost of a structure does not materially affect its choice, with the possible exception of wood structures, a reduction in cost scarcely can be anticipated by the selection of design. Reductions in costs must come from some other source. If we analyze the large divisions in Table I, we can select several items which, if reduced, will materially affect cost. These are

A. Handling of structure.
B. First cost of material.
C. Source of material.
D. Field labor.

(*A*). The handling cost of structures may be reduced greatly by the elimination of a certain amount of storage or warehousing. It is frequently possible to schedule the manufacture of structures in such a way as to permit the erection of the structure direct from the railroad car on which it was shipped. If this can be done, the storing, sorting, and reloading charges are reduced. It is recognized that this saving may be difficult, particularly at the present time, and it is realized that in order to accomplish this saving it may be necessary to resort to a certain amount of car demurrage charges which today are not to be tolerated. But, during normal times, handling charges may be reduced by this procedure.

(*B*). The tabulations show a structure cost for steel at 5 cents a pound, also for steel at 7 cents a pound. Although this is approximately the spread in the cost of steel during the past two years, it is also a common differential between the cost of fabricated shapes and structures fabricated with lacing. The cost of steel can be greatly reduced by the choice of fabrication. Briefly, structures built with H-sections (wide flange or *CB*) reduce cost, while structures fabricated with corner angles and lacing increase costs. There are many reasons why laced columns and beams must be used, in some cases to reduce weight and in other cases to secure strength, but in general the simple shape such as the H-section, for both the column and the beam is to be favored for 2- and 3-track portals.

(*C*). In general, structure cost can be reduced by securing the material within a reasonable distance of the point of application. This is certainly true for wood. A western red cedar pole transported from the West Coast to the East incurs a large freight cost. This is also true of a southern pine pole that is carried too far into the West. Ultimately, cost is re-

Figure 10. The 2-track portal structure built with shapes is usually quite economical, Delaware, Lackawanna and Western Railroad

Figure 11. To reduce field labor, brackets, cross arms, and insulators may be attached to the pole. Then, the entire structure may be erected as a unit

Figure 12. The shallow hole for this structure can be dug with off-track equipment while the deep hole usually requires hand digging

sponsible for the selection of the structure. A local product is cheaper than a product that is transported a long distance.

(*D*). Another means of reducing structure costs is to eliminate as much field work as possible. Field work is expensive, particularly because it is maintained at a disadvantage. Track availability, portable shops, and the general delays incident to outdoor work greatly increase the cost of field labor. Therefore, if possible, as much fabricating as consistent should be accomplished in the plant of the builder. This is also true for wood construction since it is possible to frame the poles before distribution. Brackets, crossarms, and insulator strings can be assembled units for quick attachment to the pole.

A single-track railroad offers a decided handicap to the construction crew since track availability is not sufficient to permit good efficient timing. In an 8-hour shift the track may not be available over two or three hours for the operation of a work train. On a double track railroad the availability may not be much better. Therefore, off-track equipment becomes a suggested solution. Although there are many sections where off-track equipment cannot be applied, most railroads are built over sufficient flat country to permit from 40 to 85 per cent erection with off-track equipment.

If steel is shipped from the fabricator on flat cars, ready for erection, there is not much to be gained by transferring the steel to the ground and erecting with a tractor-crane. However, it may be considerably quicker and cheaper to distribute wood poles from a supply train or truck and erect with the off-truck crane.

Excavations for steel structures may be broad and shallow or narrow and deep. This depends on the structure type, whether pin-end or fixed-columns are to be erected. The fixed type requiring a side bearing footing necessitates a comparatively deep excavation while the pin-end structure can be set on a shallow flat footing, thereby eliminating the necessity of digging a deep hole, possibly in a fill consisting of broken rock. The type of structure is based on design which in turn is influenced by cost. Several recent estimates indicate that with present-day material and labor costs, the pin-end type of structure is the cheapest, if the concrete footings are taken into consideration. The shallow hole can be dug with off-track equipment while the deep hole usually requires hand digging.

For wood poles, it is possible to use a boring machine in certain portions of the country, particularly the plains and desert sections, but, as a general rule, the boring of holes does not show a saving over hand digging.

Heretofore, concrete trains have been used on many large eastern electrifications. The concrete train involves the carrying of cement, water, sand, and gravel. It also involves lost time due to interference with regular trains. Some recent estimates indicate that this method of handling concrete is not quite as efficient and not quite as cheap as the centralized ready-mix plant which may be located at intervals of 5, 10, or 20 miles along the electrification. If the centralized ready-mix plant is located at 10-mile intervals, the longest haul is in the vicinity of 5 miles and this may be made with either a truck or a comparatively high speed train consisting of a light engine, Diesel or steam, and sufficient flat cars to carry the trucks. The same concrete truck that is used for the highway can be loaded on the flat cars, or several revolving mixers can be permanently mounted on flat cars. The principal saving with this arrangement is in the hauling of raw materials, also in the time required to carry the concrete to the excavation. There is greater track availability if the short train is used and in many districts trucking the concrete saves time. It has been estimated that as much as $5.00 per yard of concrete and

Figure 13. Cast attachments on concrete pole for spans and guys

Table I. Summary of Costs of 2-Track Structures for 300 Feet of Electrification

	Steel Portal	Steel Cross Span	Steel Bracket	Wood Cross Span
For steel at 5¢ per lb	$ 870	$ 965	$ 910	$ 890
For steel at 7¢ per lb	1,030	1,065	1,030	890
Cost of concrete and excavation increased $5 per yd	1,080	1,125	1,100	890
Labor increased by 50 per cent	1,140	1,180	1,160	1,025

Figure 15. Catenary span using a main messenger, an intermediate messenger, and two contact wires on Canadian National Railways

2,400 volts direct current

excavation can be saved with this procedure.

Attachments

Heretofore most attachments to steel structures have been made with fabricated shapes usually manufactured by the structural steel company. For permanent locations on the structures this method of attachment is quite satisfactory; however, there is always the necessity for adjustment and alignment. Clamped attachments for the support of insulator strings, pulloffs, and steadies provide a means of adjusting these assemblies. If the assemblies can be quickly adjusted to their final position there is a saving in field labor. Also, clamped attachments eliminate the necessity of drilling the main members of the structure.

Probably the greatest saving in the cost of attachments for wood poles for single-track construction is to be secured by the use of the angular tee-bracket which, due to its extension below the messenger cable, offers an ideal means for fastening pulloffs and steadies. The tee section provides an excellent section for cast clamp attachments and the sloping leg provides a means for adjustment, both horizontally and vertically. This method of attachment eliminates direct attachment to the pole itself. Therefore, another saving in labor is secured.

Recent electrifications employing concrete poles have been built entirely with pole clamp attachments rather than with multiple holes in the poles for fastening spans, pulloffs, steadies, and guys. Multiple holes are required for adjustment. Cast or forged pole attachments for concrete poles save construction cost because they permit quick adjustment.

Distribution of Materials

Probably one of the easiest ways to waste money on a construction job is to neglect the planning of material distribution. The cost of distributing and warehousing can run as high as 5 per cent of the total cost of construction, or it can run as low as $1^1/_2$ per cent. The difference in these two extremes is the penalty paid for inadequate planning. The higher cost may come from rehandling too many times, or it may be attributable to storage costs. It is to be remembered that material on the job is an investment, and as such, commands an interest rate, the same as any investment.

The careful planning of material distribution involves a knowledge of all materials necessary for the installation, as well as of the location and use of the materials. As an example, a completed structure may be equipped with such attachments as insulators, messenger clamps, pulloffs, or steadies depending on the purpose of the structure. At the proper time all of these materials must be gathered together and distributed for each structure, preferably when the supply train or truck is delivering other material to the same location. If the fittings and insulators are conveniently crated for handling, the work becomes easier and faster and the cost of distribution is less.

For a wood pole installation most of this equipment can be delivered with the pole, itself. To illustrate, when the pole is unloaded from a work train or truck, other equipment and attachments can be unloaded simultaneously. This procedure saves time, assures the delivery of the required materials to the proper location, and permits the linemen to assemble the wood structure without delay.

Field Prefabrication

With a knowledge of structure dimensions, there is every reason to prefabricate most spans before outside erection is started. Cable lengths for guys and spans can be cut, bundled, and tagged for

Figure 16. Simple catenary span with single contact wire on Canadian National Railways

2,400 volts direct current

Figure 17 (left). Simple catenary span with two contact wires on the Sorocabana Railway, Brazil

Figure 18. Simple catenary span with 50-foot subspans on ore haulage tracks of the Phelps-Dodge Corporation, Morenci, Ariz.

the various structures. Cable sockets, certain clamps, and insulators will be included in these assemblies. With this procedure cable assemblies can be distributed with the hardware and fittings, or even when the structure is distributed. For wood pole lines, it is easily conceivable that a completely assembled structure may be delivered by truck, the assembly having been made at some nearby location where a material center has been established. It is particularly true for the single-track structure.

There is one important procedure to keep in mind with respect to the labor costs on structure assemblies. Failure to recognize this procedure is apt to cause high construction costs. The procedure is

1. Fabricate the structure as far as possible in the plant of the manufacturer.
2. Make all attachments and perform as much of the remaining assembly work as possible on the ground before erection.
3. Keep the work train time to a minimum. It cannot always appear when it is wanted.

Insulators

The erection of insulators may not be possible at the time the structure is set, but if we take a lesson from the transmission line builder we will discover that many transmission towers for high voltage lines, carrying a long string of insulators, are erected with all hardware and insulators in place. It may be necessary to protect the insulator during the erection of the tower but this is an incidental cost compared to that of climbing the tower, pulling up the insulator string, and attaching to the crossarm. Likewise, if the insulator string can be assembled on a wood pole structure prior to setting, and the entire assembly raised at one time, it is possible to save the time of climbing the pole to erect the insulators.

Catenary Spans

For a number of years the trend in catenary span design has been towards an intermediate cable suspended from the main messenger cable. The contact wires are supported from the intermediate cable. Recent observations on several installations apparently indicate that some of the simpler catenary designs are preferable and, due to less complexity, are cheaper and easier to erect. We refer to the simple catenary span with the single large contact wire, also the modified simple catenary span supporting equilength subspans.

As examples, we refer to the recent progression of electrifications on the lines of the Sorocabana Railway in Brazil and the main line electrification of the Utah operations of the Kennecott Corporation in Utah. Both are 3,000-volt d-c electrifications. The Sorocabana installation uses the simple catenary span with two contact wires for high currents. The intermediate wire was omitted. This is not a new idea, having been employed on the first Milwaukee electrification. The Kennecott main-line installation with 250-ton locomotives was built with the subspan, utilizing a main messenger cable, an intermediate cable, and one contact wire. However, this system differs radically from the usual compound type of catenary span in that the intermediate wire actually serves as a main messenger cable for short 50-foot catenary spans. The intermediate wire is supported at 50-foot intervals by the main messenger cable, thus requiring three main hangers on a 150-foot span. The 50-foot subspan in turn supports the single contact wire with three short hangers or clips, two of which are of the same length. The contact wire is 350,000 circular mils and performs the same function as two contact

Figure 19. Simple catenary with 400,000 circular mil contact wire on haulage way Pittsburgh Consolidated Coal Company

Figure 20 (left). Rodpulloff assembly attached to T-bar bracket; Chilean State Railways

Figure 21. Rod pulloff assembly aligning two contact wires; Sorocabana Railway

wires on many other electrifications. Incidentally, higher currents than those encountered at Utah are being collected on a simple catenary system of the Pittsburgh Consolidation Coal Company near Pittsburgh, Pa., where the voltage is considerably lower. It is recognized that these simple catenary spans and single contact wire spans are in use on the Reading, the Great Northern, the Pennsylvania, and the Milwaukee, and these railroads are not operating at slow speeds.

The amount of current collected by the pantograph has considerable bearing on the design of the catenary span. A simple span constructed with loop hangers and with large copper equivalent in the messenger cable as compared to the contact wire, may cause burning of the messenger cable and hanger loop because of high current through the hanger. Heretofore, it has been the practice to select a compound catenary span for the higher currents. This span makes use of clamped joints on all wires and cables, thus eliminating the possibility of burning due to hanger movement. However, currents of greater magnitude than formerly permitted can be carried through a simple catenary span if the ratio of conductivity of the main messenger to contact wire is reduced. This is accomplished by using a larger contact wire and at the same time reducing, somewhat, the conductivity of the messenger cable. This has been done on a number of installations. Furthermore, greater current can be permitted through the flexible catenary hanger if the messenger cable is properly protected with a sleeve or shim.

Naturally, the simple catenary span has greater application on the higher voltage lines where less conductivity is required. We refer to the 11-kv lines. Where these higher voltages are used the messenger cable may be a high-strength composite cable, the chief function of which is to support the contact wire. Naturally on long spans there is a lower limit to the size of the main messenger cable or, we might say, to the weight per foot of the system. Conductivity ceases to be a factor in this weight problem and a minimum weight per foot is finally reached on the basis of strength and structural requirements.

With respect to high speeds it is believed that a more rigid catenary system is possible providing the collector has sufficient sensitivity. This problem is similar to the track problem. Some years ago a resilient track was necessary for the rigid truck and spring suspension on freight and passenger cars, while today, particularly with passenger cars, the spring suspension is such that a more rigid track is possible, and these cars are certainly operating at higher speeds than the older types. Therefore the large contact wire which is considerably more rigid than the 3/0 and 4/0 types can be used for high speeds, and the heavier contact wire has a tendency to "weight" the system and retard the usual wave in the contact wire preceding the collector.

We must not forget when we are discussing simple catenary that there are systems such as the Chicago, North Shore and Milwaukee Railroad which operate at speeds in the vicinity of 80 to 90 miles per hour with direct suspension, and the collection of current is considered to be satisfactory. This does not mean that the simple catenary span, which has better characteristics than a direct suspension span, is possible for high speeds.

The usual practice is to erect catenary spans with a work train. A considerable saving is possible by limiting the work train to the stringing of messengers and cables. Other span work can be accomplished without the work train.

There is nothing to be gained by stringing messenger cables and other wires from trucks or from other off-track equipment. So far, the work train is preferable. However, there are many operations that, heretofore have been accomplished with the work train that can be handled in another manner. We refer particularly to the attachment of the catenary hangers, messenger sleeves, and duplex clips. Experience has shown that these can be erected by a 2-man crew, one man sitting in a boatswain's chair while the

Figure 22. Two-track steady; Sorocabana Railway

Figure 23. Single-track triangular steady—bent T-bar bracket provides adjustability; Chilean State Railways

other man is a ground attendant. As many 2-men crews as necessary can be scattered over a system for the purpose of maintaining the construction schedule. The resulting cost of erection is below that with the work train.

Pulloffs

There have been many revisions in pulloff design, most of which have simplified the device. Several recent installations have been built with simple rod pulloffs that are light in weight and comparatively cheap. Some of these installations have required the 3-rod pulloff for the alignment of an intermediate cable and two contact wires, while others have required the 2-rod pulloff for simple catenary with two contact wires. There is also a third type that has been installed on the subspan catenary which requires one rod attachment to the intermediate cable and one to the contact wire. All of these pulloffs are built with straight rods converging on a pulloff casting where rod length adjustments can be secured.

For single-track bracket construction the pulloff is attached to the insulator string which in turn is attached to the T-bar bracket. The insulator attachment to the T-bar bracket is adjustable along the axis of the T-bar, thus providing a quick means for trolley wire alignment. Simplicity in design of both the pulloff and the attachment will reduce construction costs.

Steadies

For this discussion two types of steadies will be described, namely, a 2-track steady for cross span or portal structures and the single-track steady for a bracket arm.

The 2-track steady which has been installed on many miles of the Sorocabana Railway in Brazil is not attached to the supporting structure. The steady assembly is constructed just by carrying a cable span between the two main messenger cables. Insulation is placed in the center of this span. On either side of the insulation, a steady rod is carried to the

Figure 24. High work train cost is usually due to lack of track availability

contact wire or to the intermediate cable. It will be noted from Figure 22 that with this "X" construction the contact wires, although permitted to move a slight amount, cannot swing to a dangerous position. Usually with this design it is necessary to erect the supporting string of suspension insulators at an angle, as illustrated, thus providing greater stabilization by creating a higher mechanical load in the steady span between the two messenger cables.

A steady span for single track can be built with a triangle of rods, two corners of which are attached to insulator strings

Figure 25. There does not seem to be any substitution for the work train for erecting steel structures

and the third corner to the intermediate cable or to the contact wire. The upper corner of the triangle is attached to the supporting insulator string, while the outer corner is attached to another insulator string which in turn is supported by the T-bar bracket. Analysis of this arrangement will show that there can be no movement to the right since the lower rod of the triangle and its insulator string become a pulloff. If the wind is from the right, there is a tendency for the lower section of the triangle to travel to the left and at the same time for the left-hand corner of the triangle to elevate. With this action there is some movement of the trolley wire to the left but the movement cannot become great since left-hand movement of the trolley wire also tends to raise the trolley thus retarding the sway. This type of steady is in use on the Sorocabana Railway, the Chilean State Railways, and the main line 3,000-volt d-c electrification of Kennecott Copper Corporation in Utah.

Rail Bonds

For heavy currents where it is necessary to use a bond of 4/0 capacity or greater there seems to be no cheaper bond than the short U-shaped bond welded to the rail. Although there are several installations of arc weld bonds on systems where the trolley voltage is above 600, it is general practice to use a gas weld bond for electrifications with higher voltage. It is usually cheaper to install the gas weld bond where higher voltages prevail.

For the a-c electrifications, such as 11 kv, American practice has proved that the light head-of-the-rail signal bond is ample. The Pennsylvania Railroad has installed many head-of-rail bonds that do not require welding. The cost of bonding for this type of installation is approximately half the cost of the equivalent welded bond.

Basic Materials

Since the choice of materials readily can affect cost, a short discussion on their selection will indicate where these savings are possible. The major tonnage of material is to be found in the structures. Structure material is determined partially by geographic location, track conditions, traffic density, number of tracks, and expected life of the structure.

Geographically there are many reasons for the omission of wood in certain parts of South America. The tropical climate may be responsible for decay in some locations, while in other locations, termites or other wood destroyers prevent

Figure 26. By reducing the work train to a miniature, work train costs also are reduced; Cleveland Union Terminals

its use. Concrete or steel is the answer. Along coastal sections steel structures must be well protected from salt, otherwise wood or concrete may be necessary. Concrete structures, like steel structures, also have a maintenance problem due to the corrosion of reinforcing bars.

When it is said track conditions affect the choice of structure, reference is made to the condition of the soil. It may be uneconomical to install a long-life structure due to slides or to the shifting of materials in cuts and fills. This condition is found on newly built tracks and on the large open-pit mine electrifications.

Traffic density influences the choice of structure. More trains mean more electrical load, and more electrical load means heavier structures. It is difficult to beat the first cost of a wood structure for a single track railroad, but the "density of traffic" factor may throw the choice into steel structures. This can be determined only by an economic study.

The number of main line tracks is based on traffic density, therefore, what has just been said about traffic density applies equally well to the choice of material for more than one track. Steel is usually favored for multiple track construction, if for no other reason than appearance, which, incidentally, is a real factor in electrification.

The expected life of a structure must be based on the life of the electrification. A short-time electrification may be constructed with wood since replacement may never occur. On converse, our big carriers would not consider short-life material if replacement is to be anticipated many times during the life of the electrification. Our western roads have found wood structures to be economical because maintenance and replacement costs have been comparatively low. The reverse is true in the east.

The choice of messenger cables is also greatly dependent on the amount of electric energy transmitted over the catenary system. If the amount of energy is high the copper equivalent in the distribution system will be high. If the amount of electric energy is low, the conductivity of the system is low. For a high current system, the cables are copper or a composite of nonferrous materials. Likewise fittings such as hangers and clamps are made of high conductivity or nonferrous material because they are current carrying. For a low current system a nonferrous messenger cable may not be necessary since the contact wire may have sufficient conductivity adequately to handle the electric load. This is also true of hangers and clips. They will not carry much current. Therefore, from a current-carrying standpoint, the choice of material, ferrous or nonferrous, in the overhead system is partially controlled by the amount of electric energy to be carried.

Corrosive atmospheres also affect the choice of materials. There are many overhead systems built for relatively small current that could have been constructed with iron fittings, properly protected, rather than with nonferrous materials. Many systems have been built with ferrous materials and after 20 years of operation are still in good condition. Reference is made to such installations as portions of the Milwaukee Railroad and Canadian National electrifications, also to many of the large industrial operations in the western United States and in several foreign countries. Malleable iron fittings properly galvanized, have an exceptionally long life even in the presence of certain atmospheric contamination. The choice of material for the overhead system does affect the cost of the installation and consequently should not be made until the conditions of atmospheric contamination are known, and until material behavior under these conditions has been determined.

Work Train Cost

One of the largest items of cost for the overhead distribution system is chargeable to the work train. The high cost is not necessarily due to train and crew alone, but to lost time caused by the lack of track availability. There are examples of track availability of only a few hours, in fact there are locations, due to heavy traffic density, where availability is less than 2 hours in a 24-hour period. With this picture of work train cost it certainly can be concluded that either there must be greater track availability or there must be less work train operation.

It is quite difficult to increase track availability, particularly on the 1- and 2-track railroads carrying a large volume of traffic. It is, however, possible to increase track availability by bunching freight trains or by planning certain train delays, but the net gain is not big and will not account for an appreciable reduction in costs. The greatest savings is to be attained by eliminating as much work train movement as possible, by substituting off-track equipment, and by using

Figure 27. Push-car used on recent electrification of the Sorocabana Railway, Brazil

additional ground crews. There does not seem to be any substitution for the work train for erecting steel structures or for stringing cables, but wood structures may be erected with off-track equipment or even with ground crews, and such devices as hangers, clamps, and feed taps can be erected with the aid of a boatswain's chair.

Another means of reducing cost is to reduce the size of the work train, in fact reduce the work train until it becomes a miniature. Some of the electrifications back in the 30's took advantage of the small gasoline car, also the ordinary push-car used for track work. The Reading and the Cleveland Union Terminals used small self-propelled cars and found them to be quite economical and satisfactory. Small gasoline-driven cars were used on such recent installations as the Morenci operations of the Phelps Dodge Corporation for almost all types of distribution work with the exception of cable stringing, and even this was attempted but ultimately abandoned because the car was too light to hold the stringing loads by mere track adhesion. Although this light equipment must be treated the same as a work train, in that it must be controlled by the same orders and clearances, it is by far the most flexible of the two types of work train equipment since it can be removed from the track and rerailed at points other than standard track turnouts.

The small self-propelled cars can be housed on the job. It is not necessary to return them to a terminal for fuel or overhaul. They are a part of the tool equipment, and as such, represent an appreciable reduction in work train cost.

Clearances

The second main subject pertinent to cost reduction is "clearances.' The word, itself, seems harmless enough, but to the distribution man it spells cost. Probably an example will clarify this statement.

At the present time the Kennecott Copper Corporation is building a main-line 3,000-volt electrification between the Bingham Mines in Utah and the mills at Arthur and Magna. The catenary system is being built over new track; in fact, the entire roadbed is new. Here is an installation that is not hampered by existing steam facilities, low highway structures, yard restrictions, or any other limitation that becomes the nightmare of the designer when planning overhead for an existing steam railroad. In this particular case the designer could proceed with the minimum of lost motion, could produce standard designs for application on similar stretches of track, could call for highway structures with the proper overhead clearances, could disregard telegraph and communication lines; in fact, actually could produce the finished line on paper, knowing that the system would be built as planned. If the designer of this system were to move to one of our big existing railroads and attempt to design along the same lines he would be greatly hampered by running into innumerable problems unheard of on the Utah installation. For instance, we will take the subject of contact wire height. Every operating man will demand a trolley wire height of at least 22 feet but on an old railroad this specification must be violated many times. On the Utah installation the desired height of trolley wire has been maintained at all locations. Bridges and other limiting structures have been built to secure this height.

Figure 28. Gasoline-driven car used for overhead construction on the Morenci operations of Phelps-Dodge Corporation

On the existing railroads, many bridges and signal structures have been erected for a period of years. The crowding of overhead wires in these restricted locations becomes quite a feat. Although the operating department of a railroad usually demands a high wire in all locations there are many exceptions caused by bridges, tunnels and other restrictions where physical limitations existed prior to the electrification study. In some respects this practice seems redundant. It is not good practice to permit trainmen on the top of trains where high voltage wires are suspended above their heads, except, of course, in an emergency. Therefore the lowering of the overhead system to permit a contact wire height of 20 feet, except at highway crossings, cannot be too serious and a decided saving in structure costs is possible. The contact wire height on the catenary system of the Cleveland Union Terminals is 19 feet.

Figure 29. Offset catenary on haulage of Columbia Chemical Company, Ohio

One method proposed for the maintenance of a high overhead clearance and at the same time reduce costs, is to offset the catenary system from the center line of track. This scheme of "have your cake and eat it too" provides steel structure clearance over the track of 22 or 24 feet

Figure 30. It is not necessary for the railroad to detail completely the supporting structures

Figure 31. Ground crews save work-train cost

since the catenary system is offset to the right or left. The contact wire is lowered to an elevation of 19 or 20 feet. Although this method of construction may require a redesign of the collection equipment, the anticipated savings seem to be sufficient to warrant the cost of development of a new collector. For single- or double-track installations it may be possible to secure attractive savings in structure costs due to the lower positions of the mechanical loads.

Psychological Barriers

The third main subject relative to cost reduction is "psychological barriers."

All engineers work against a certain barrier when starting a large project. The effect of the barrier usually is evidenced in the planning of the engineering work and represents to a certain extent the "unfamiliar" phase of design. As an example, all installations are based on a cost estimate. If the construction crews meet the estimate, the job is considered to be economical but if the cost of construction is greater than the estimate, there is bound to be some doubt as to the economic outcome of the job. As a result, the planning or engineering department is apt to "play safe" wherever possible. One place where the engineering departments for steam road electrifications have been playing safe is in steel design.

It is the task of the railway's engineering department to select the general design of structure and to locate the structure advantageously along the right of way. If economics are to be considered it is not the task of the engineering department to design the structure. Many electrifications have cost too much because of too much engineering. In the case of the steel structure, many railroad engineering departments have detailed completely every column, every truss, every knee brace, and then, after submitting the designs to the fabricator, the fabricator has redesigned every structure. This duplication of work is costly. The real answer is, "let the fabricator detail the steel, he will do it anyway." This procedure is also logical for other classes of design including transmission systems and catenary systems. After the general schemes have been selected, there is no reason why the burden of transmission and catenary design cannot be boiled down to a "system design," then let the manufacturer design the fittings.

It has been estimated that as much as three per cent of the total cost of an installation can be saved by eliminating duplication in design. There is no need to carry the structure design beyond the space diagram, and there is no need to carry the catenary design beyond the general scheme. Further attempt at design in both cases is simply duplication and is very costly.

Future Considerations

This paper has emphasized certain means for the reduction of costs of catenary distribution systems. Let us review a few of these means, also add a few suggestions that, today, may not be quite as evident as the ones discussed.

1. The shallow footing for structures suggests a means of saving cost by permitting the use of mechanical digging equipment. The hole for the footing must be large; therefore a large clam shell or similar type of bucket is possible. This equipment may be mounted on a tractor, thus removing the track availability factor.

2. A centralized concrete plant offers certain savings over the concrete train as evidenced by its use on many expressway installations. Many building contractors use ready mixed concrete because it is cheaper. Our city transit systems use ready mixed concrete for the setting of thousands of steel poles for trolley coach overhead construction. They have found it to be cheaper than concrete mixed by other methods.

3. Off-track equipment saves work train cost. Off-track equipment consists of material trucks, concrete-handling trucks, cranes for the erecting of some steel structures and wood poles, tractors for certain wire stringing, and other smaller equipment.

4. Some off-track equipment may be of the rerail type that will permit the vehicle to operate on either rail or ground.

5. Many overhead construction operations such as wood pole setting can be accomplished with a ground crew, thus saving work train cost. Only the distribution of wood poles in areas which are inaccessible by truck need be accomplished by work train. Ground crews can erect catenary hangers, duplex clips, feeder taps, and many other fittings that would require work train time.

6. Small gasoline-driven cars, also small cars with staging, drawn by the gasoline-propelled car, can be employed for many construction operations.

7. It is possible that a wider pantograph may reduce costs by permitting greater offset of the contact system at points of pulloff. Again, a different design of collector somewhat similar to the pole trolley may provide a means of cheapening the overhead system. The pole-type collector with swivelling movement also will permit an increase in offset for the trolley wire on curves, thus permitting a decided reduction in construction costs.

8. If a new type of collector is available, as an example, the pole type, structure costs can be reduced by reducing the height of the steel. If the operating department of the railroad requires a 22-foot clearance between track and overhead system, it is possible with the aid of a different type of collector to offset the catenary span some 4 or 5 feet from the center-of-track and erect the steel truss to just clear the 22-foot requirement. The catenary span would be located to the side of the center of the track and, of course, below the steel truss. Due to the lower position of the catenary span, its side loads on the structure would be reduced.

9. Higher contact wire voltages reduce the amount of copper in the overhead system. This reduction, in itself, is quite significant and represents a big saving; however, another appreciable saving probably will be found in the cost of the structure. The cost of a structure is somewhat in proportion to the mechanical loads applied to the structure. Savings in steel structure cost and conductor cost more than offset the increased cost of insulation.

10. Head-of-rail bonding with the small pintype signal bonds for high-voltage a-c

Table II

	Possible Reduction, Per Cent	
	Steel	Wood
Central concrete plant	0.25	
Off-track—crane		0.50
Off-track—small motor cars	0.25	0.50
Clamped attachments		0.50
Distribution of materials—by truck		0.25
Ground crews—cross span	0.60	0.80
Ground crews—catenary spans	1.00	1.20
Simple catenary span	1.80	1.80
A-c bonding	1.10	1.10
Offset catenary or lower contact wire	7.50	1.50
Engineering	2.00	3.00
Totals	14.50	11.15

systems will save about half the cost of ordinary bonding where the currents are low. This is not true for d-c installations.

11. Engineering costs may be appreciably decreased by giving the fabricator of structures and other materials the design work he naturally will duplicate.

Anticipated Cost Reduction

The title of this paper indicates that costs may be the stumbling block for electrification, and the opening sentence indicates that there may be possible cost reductions. It is hoped this paper has called attention to such cost reductions, but a summary of possible savings based on the suggestion of this paper may further emphasize cost reduction. Here are some figures taken from the same three estimates used at the beginning of the paper. The per cent reductions are based on the total cost of electrification as shown in Table II.

Probably there may be some criticism of these cost reduction methods, but they are based on observation, experience, and planning. If these suggestions, when put into practice, reduce the cost of electrification, it will make the Diesel and electric systems, which are both good methods of transportation, less competitive with regard to cost.

Discussion

K. H. Gordon and L. B. Curtis (Pennsylvania Railroad, Philadelphia, Pa.): This paper is a significant contribution to the literature on the economics of railroad electrification. Since a change from steam to electric operation cannot be made in relatively small units as can a change from steam to another form of self-propelled locomotive such as the Diesel-electric, and since the overhead distribution costs are a very substantial portion of the total cost of electrification, any measures which can be taken to reduce these costs are important. However, reduced construction costs never should be obtained at the cost of excessive maintenance.

While this paper is concerned primarily with single-track and 2-track electrification, a number of points are made on which, we believe, experience with an extensive multitrack electrification will have some bearing.

One of these points is referred to as "psychological barriers." It is our belief that, with an engineering organization experienced in electrification design, the engineering costs are reduced to a minimum consistent with safe and adequate construction, and while there is a natural human tendency to do things the way they have always been done, our observation has been that the experienced engineer is ever on the alert for new and better methods.

Many of the methods suggested by Birch are valuable in any electrification project, such as the maximum economical use of off-track equipment, the avoidance of duplication of effort in steel design, the use of small rail-head bonds, and, to a limited extent, the use of ready mixed concrete from a central mixing plant. The latter is chiefly of value, however in built up areas where access to foundation locations by truck is not difficult. In other locations the concrete train, a portable central mixing plant, has proved more desirable from a cost standpoint.

However, a number of the suggestions are questioned for use in an extensive multitrack electrification. Some of these are

Shallow foundations. Experience has shown that, except for certain difficult soil conditions, a deep "can-type" foundation requiring a minimum of forms and reinforcing is less costly than the shallow "gravity type" suggested.

Simple catenary. This type of construction is lowest in cost and is satisfactory for almost any electrification, and tests have indicated that the stresses set up in the wires are lower than with compound catenary. However, it is not considered necessary to reduce the conductivity of the messenger. In fact, in many cases it is desirable to increase this conductivity and utilize one or more jumpers in each span, firmly clamped to both the messenger and contact wire, to shunt the flexible hangers.

The use of light weight construction cars. It has been found that this type of car cannot be depended upon to shunt the track circuit; hence, it should not be used where the operation of trains depends upon the proper signal indication which is supposed to result from shunting the track circuit when the particular section of track is occupied.

Reduced height of contact wire. Electrification should not impose unnecessary restrictions on the operation, in locations where it is necessary or desirable to have men on top of cars with steam operation it may be just as much so with electric operation, and each such location should be studied to balance the desirability of a lower contact wire against that of continuing existing practices. The suggestion that contact wires be offset and lowered does not seem practicable for a multitrack electrification, as it would appear to restrict the direction of operation of locomotives and would greatly complicate construction at interlockings.

Pole-type collectors. These are not considered practicable for high-speed operation.

Duplication of engineering. While we largely agree with Birch's comments with respect to steel design, little such duplication has been found in the catenary system itself.

We believe the following suggestions would also reduce the over-all cost of overhead distribution when it is practicable to employ them:

1. Give engineering a sufficient start on construction so that completed final drawings may be used and sufficient material may be on hand to avoid delays.

2. Complete all construction work before energizing the system, thereby eliminating the need for working under clearances.

H. F. Brown (New York, New Haven and Hartford Railroad, New Haven, Conn.): This paper represents the thoughts of one who has been closely associated with much of the existing catenary design in both North and South America, and for that reason is a valuable addition to the existing bibliography on this subject.

While it is true that a number of existing steam roads were electrified during the first three decades of the twentieth century for urgent economic or operating reasons, to say that electrification is "progressing at a snail's pace" is hardly true in the broad sense, for the universal application of the Diesel-electric locomotive is primarily because it is an electric locomotive which carries its own power plant along with each unit. It is just as much an electric locomotive as one with pantographs or third rail shoes—and so successful because of its electrical characteristics. The railroads of the United States *are* electrifying in this sense at a very rapid rate—and the field for the manufacturer of such electric railway apparatus is a very large one today.

Birch points out a very significant fact first of all, that the cost of the overhead contact system is not greatly different from the incremental cost of the Diesel-electric over the straight electric locomotive. This never should be lost sight of by the economists studying the substitution of Diesels for steam, especially if a part of the railroad should be already electrified.

The author next points out ways and means where, in the light of past experiments and experience, such costs *may* be reduced appreciably, one of the methods being to do just as much of the construction work by means which do not interfere with use of tracks for revenue business. This should be extended to line maintenance work, after electrification.

Many of the larger installations of overhead contact systems in the past have been over multitrack railroads with very dense traffic, hence construction costs have been high. It should be, theoretically, quite a bit cheaper per track—per mile—to install overhead construction over a single-track or a double-track line than over a 3- or 4-track line, because much of the construction can be done from the wayside on the former, whereas the construction over the middle tracks always must be done largely from those tracks themselves.

Although there has been helpful design for certain hardware used in overhead catenary construction from the various manufacturers specializing in such hardware and parts used for direct suspension for street railway and, more recently, trolley coach-contact systems, nearly every railroad that has electrified has found it expedient to de-

sign much of its own hardware because of lack of existing standards and other considerations which the railways thought they needed—and with which the manufacturers often could not agree. High stress insulators are just one example. There is a greater amount of agreement and design which could be standardized today than formerly.

There are often other considerations in contact system design besides ample current conductivity and mechanical strength. For example, a line must be not only capable of withstanding heavy sleet or ice loads, but also must withstand the possible mechanical or electrical methods used to remove it. Spans in locations exposed to high wind velocities must be short enough so that horizontal displacements cannot cause pantograph trouble.

The author emphasizes another fact concerning which too little study has been made in the past—the closer co-ordination of pantograph design with the overhead design.

Although there is a decided trend today toward the increased use of Diesel-electric locomotives, there are many economic factors and adverse possibilities in the foreseeable future which easily can change the economic advantage of this type of motive power—and when this time comes the railroads are still going to demand the characteristics of this type of power, namely, electric locomotives, and Birch's paper will be found useful in those days even if there is very little construction of this type during the next four or five years.

Sidney Withington (New York, New Haven and Hartford Railroad, New Haven, Conn): Birch refers to relative progress in electrification in the United States as compared to progress in all other parts of the world. The answer lies mainly, as he points out, in scarce and expensive fuel elsewhere. We always have been a wasteful nation because we have had so much in the way of natural resources. Just now, as Birch has also pointed out, the Diesel engine is having a notable vogue among American railroad men. What the future will bring forth in the petroleum industry and in the gas turbine which may be developed to burn low grade residual oil or powdered coal will be of considerable interest.

Birch gives figures of about 27 per cent as representing the ratio of the cost of the power distribution system in an electrification project to the total cost of the entire project. It is interesting to note that in the New Haven electrification, installed at various periods during the past 40 years, the distribution system accounts for 26.7 per cent of the total capitalization as of the present time, including motive power, power plants, and substations.

It is perhaps a little unfair to blame the structural engineer of the "railroad's bridge department" for excessively heavy catenary supporting structures. It is true that the duty of the catenary supports is a very different type of duty as compared with that of railroad bridges, but it is also true that the power transmission and distribution facilities installed directly over busy railroad tracks where heavy trains are operated at high speeds present many problems to the railroad designing engineers which the designers of power transmission lines do not meet. A higher mechanical factor of safety for the railroad facilities is very necessary as compared with ordinary transmission lines. This applies to steel structures, wood poles, catenary cables, and strands and hardware.

As Birch has pointed out, wood poles offer some very intriguing advantages, where they are available without too much transportation cost. It should be borne in mind, however, that even with proper treatment, the life of a wood pole is not unlimited, and general replacement of wood poles in a busy electrified section of railroad may be a major headache for those responsible for continuous operation of the railroad.

The author mentions the advantage of rolled H sections as compared with lattice construction. This is an important consideration even apart from first costs. Painting the structure must be done periodically regardless of the design, and painting a light lattice or laced structure is a very expensive process as compared with a solid member. Some railroads, incidentally, have used rolled H beam design for four tracks as well as for 2- and 3-track sections.

Off-track material assembly and erection has such obvious advantages, especially with modern mobile equipment, that it should be seriously considered by all responsible. It is, however, true that on many railroads, especially those in congested territory where rights of way are restricted or in rough terrain where there are numerous cuts and fills, the use of such equipment is likely to be limited.

Birch points out the advantages of portal structures which are self-supporting so far as loads across the tracks are concerned, even though they may require somewhat heavier steel. It may be said in this connection that in designing the foundations for such structures there must be some allowance made for possible loads *along* tracks on account of broken lines or other abnormal conditions, and also that, especially where deep frost may be experienced, the foundation must be carried down below the frost line if settlement is not to cause trouble, especially on fills.

The author touches briefly on catenary design. A large book might be written on this phase of the subject, and even then would be likely to cover but a small part of the problems which are met. The flexibility of the contact system is tied closely to the pantograph design. A very important factor often overlooked is wind loads and horizontal stability, epecially with long spans and at exposed locations. The use of noncorrodible materials has been of increasingly greater interest on existing electrification, as deterioration of carbon steel members has been experienced with the passage of time, and expensive replacements or frequent painting have been found necessary. Noncorrodible material is expensive in first cost but may represent attractive savings in the long run.

Birch mentions the use of small gasoline-driven construction cars for erection on busy tracks. One important limitation in such equipment which must be kept in mind is that it may not be heavy enough to operate track signal circuits, so special protective methods must be used to avoid trouble.

Adequate clearances over track for the catenary are important, even though they must be reduced at overhead highway bridges, and even though it may be practicable to prohibit men working on tops of cars. A low trolley may increase the difficulty in cleaning wrecks or damaged pantographs on motive power. The offsetting of the contact wire from the center of the track, which Birch suggests, is of little advantage so far as permitting men safely on tops of cars is concerned. If a man *can* reach the wire from the car he will be sure some time to do so.

This paper is a valuable contribution to the literature of catenary design, and the Institute is to be congratulated in having obtained the data which he has presented.

L. W. Birch: It is always gratifying to receive discussion of one's paper, particularly if the participants in the discussion have considered the subject worthy of a written discussion. These discussions uncover other's thoughts—new angles, and may even be controversial to the extent of offering quite different solutions. The author appreciates the additions that Gordon and Curtis of the Pennsylvania Railroad and Withington and Brown of the New Haven Railroad have made to his paper. In an effort to answer the questions arising from the discussions, provided by these four discussers, the following brief explanation is presented on the most important subjects.

(K. V. Gordon and L. B. Curtis) 1. With respect to the reduction of engineering costs, the paper deals particularly with the duplication of costs for steel design. Frequently, the railroad will detail all structural pieces, a job which the structural company will later redesign. This duplication is costly, and is paid for the second time to the structural company.

2. Reference is not made to gravity footings in the paper. The author particularly described slab footings similar to those used on the Lackawanna Railroad.

3. When the statement was made that the use of a large contact wire would permit the decrease in the conductivity of the messenger cable, it was not meant that the total circular-mil capacity of the system should be reduced.

4. It is true that lightweight construction cars may not operate signals. However, this does not necessarily eliminate the use of the equipment. There are many tracks where lightweight equipment can be used without any particular effect to train operation.

5. There is no particular complication to the use of offset catenary. In fact, it is in use on a number of industrial electrifications. Offset catenary will permit the lowering of the system, and as a consequence, a reduction in cost can be secured, due to the lesser moments encountered in the steel.

6. The pole-type collector referred to in the paper does not include the conventional street-car type. Pole-type was merely a term used to describe a wiping type of collector, not a pantograph type. It might even include the bow type. Incidentally, a conventional pole collector with shoe is operating in and out of Chicago on trains running 90 miles per hour.

(H. F. Brown) 1. With respect to standardization of hardware and insulation, it is agreed that there have been many designs which duplicate earlier work. However, of later years, most steam railroads have

recognized the benefits of standardization, and as a result there is not so much duplication. As an example, such early electrifications as the Illinois Central and one section of the Canadian National used $7^1/_4$-inch suspension units for 3,000 volts direct current. During the same period, the Cleveland Union Terminals and the Lackawanna used 10-inch suspension units for the same voltage. During the past eight years, the 10-inch unit has been selected for practically all 3,000-volt d-c electrifications—example, the Canadian National Railways and the Chilean State Railways. All 11-kv systems have used the 10-inch suspension unit.

With respect to hardware, there has been some attempt to standardize such items as the catenary hanger. As an example, the Illinois Central, Cleveland Union Terminals, Chicago South Shore and South Bend, and the Canadian National Railways have used one type of hanger over a period of 22 years, new installations having occurred intermittently throughout this period.

2. High strength suspension units employed in dead-end work have been standardized during the past 10 years, with the result that the 25,000-pound unit could be considered a standard. The 15,000-pound 10-inch suspension unit has been used almost universally for tangent construction.

3. It is agreed, absolutely, that the collector designer and the overhead designer should co-ordinate their work at all times. Incidentally, mention was made of a pole-type collector earlier in this rebuttal. The development of this collector must be conducted by the collector designer, and the overhead engineer must co-ordinate his efforts with the collector designer.

(Sidney Withington) 1. There would be little point in recommending wood poles for construction in the eastern section of the United States; however, the West and the South can erect wood poles economically and expect a fair life from their local timber. Particularly in the West, the cedars can be erected and maintained for single-track construction cheaper than most steel. This is true in the South, where the full-pressure-creosoted pine pole is obtainable without much freight cost.

2. Off-track equipment can be used on the greater portion of all railroads. Referring to one of the examples used while making the estimate for my paper, the western railroad crosses the Rocky Mountains, also a portion of the Colorado-Utah desert. It was found that more than 90 per cent of this railroad could be served with off-track equipment for the purpose of erecting poles, digging holes, and attaching hardware for electrification.

3. The Lackawanna footings are approximately four feet in the ground. They are slab footings, not necessarily gravity footings. It is apparent from recent inspection, that this depth has been satisfactory. It is agreed that the footing must be of sufficient depth to prevent frost interference.

4. A 19-foot contact wire scarcely can be considered a low wire when it is used over a great many miles of track and throughout the entire Cleveland Union Terminals electrification. There are many miles of "low trolley wire" on other roads, where it is necessary to reduce height because of bridges and other physical limitations.

Shunt Capacitor Installation for Single-Phase Railway Service

H. F. BROWN
FELLOW AIEE

R. L. WITZKE
MEMBER AIEE

A 10,000-KVA BANK of shunt capacitors recently placed in service on the 22 kv electric traction system of the New York, New Haven, and Hartford Railroad, is the first installation of this kind to be made on a 25-cycle single-phase system. Made up of 25,400 kva of 60-cycle 15-kva units, it is also one of the larger capacitor banks in operation. The installation is tuned by means of series reactors to control both the third and fifth harmonic voltages on the traction system. The units are automatically switched in steps of approximately 2,500 kva each. This reactive supply has increased the traction system voltage by as much as 20 per cent, and has released 6,000 kw in generating capacity during peak load conditions. In addition, it will save an estimated $20,000 a year in cost of energy losses by decreasing the hours of operation of several large frequency changers, previously operated much of the time as synchronous condensers for voltage control.

This paper reviews the conditions giving rise to the need for additional reactive capacity, compares the relative costs of synchronous condensers and shunt capacitors for 25-cycle single-phase service, and discusses the problems incident to the installation of capacitors on a railway system. The general characteristics of the capacitor station are given in some detail. Six months operating experience, and test results are reported.

The Railway Traction System

The initial electrification on the New York, New Haven, and Hartford Railroad, made in 1907 between New York City and Stamford, Conn., was operated at 11,000 volts 25-cycles single-phase, with power supplied by the railroad-owned station at Cos Cob. The present 3-wire system, Figure 1, was installed in 1912 just prior to the extension of the electrification to New Haven in 1913. The 3-wire power distribution system is supplied from the 11 kv, single phase generators at the supply points through 11/22-kv autotransformers, the midpoint of the transformers being connected to the rails. Balancing autotransformers are connected to the trolley and feeder circuits at suitable intervals along the 4-track electrified section, the spacing of the transformers being determined primarily by track switching requirements. The traction load is all on the 11 kv trolley-rail circuit, the transmission between the power sources and the balancing transformers being at 22 kv over the trolley-feeder circuits.

The present power supply consists of the railroad-owned station at Cos Cob, a tie at West Farms (East 174th Street, New York) to the Consolidated Edison Company Hell Gate Station; and four variable ratio frequency changer sets—one at East New York; one at Station *A*, the power station of the railroad-owned street railway subsidiary at New Haven; and two at Devon, Conn. for supply from the Connecticut Light and Power Company, Figure 2. Their capacities are indicated in Table I.

The system traction load has peak requirements as follows:

Maximum peak hour, 50,000 kw
Maximum peak 15 minutes, 57,000 kw
Maximum peak 5 minutes, 63,000 kw
Maximum swing, 72,000 kw

These loads usually occur between the hours of 5:30 p.m. and 6:30 p.m. on days of heavy weekend or holiday travel. The system power factor, measured at the sources, is between 70 and 73 per cent, which means that the reactive demands are approximately equal to the power demands. The system load factor is about 56 per cent. Occasional light load periods occur when the minimum hour is about 15,000 kw. A study of Table I indicates a deficiency in reactive capacity, particularly with one machine out of service at Cos Cob.

The ever-shifting nature of the railway load presents additional problems. The 22-kv transmission precludes the possibility of transferring the entire output of any one supply station to the extreme load centers on the system. The peak load center is well east of Cos Cob, approximately 60 per cent of the load being east of that station during the peak hour. The fact that the voltage at West

Paper 48-39, recommended by the AIEE land transportation and transmission and distribution committees, and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26-30, 1948. Manuscript submitted November 12, 1947; made available for printing December 11, 1947.

H. F. Brown is electric traction engineer with the New York, New Haven and Hartford Railroad, New Haven, Conn. and R. L. Witzke is central station engineer, industry engineering department of the Westinghouse Electric Corporation, East Pittsburgh, Pa.

This installation represents the co-operative efforts of the engineering staff of the railroad; of their consultants, Gibbs and Hill, Inc., who constructed the station; and of the manufacturer, Westinghouse Electric Corporation. The members of all these groups have contributed largely to the data in this paper. Particular mention must be made of the help of S. S. Watkins (F '46) and P. Goldstone (deceased) of Gibbs and Hill. A large measure of credit is due to engineers of the Southern New England Telephone Company, the American Telephone and Telegraph Company, and Bell Telephone Laboratories for their help in making the detail tests on the installation.

Figure 2. Location of power sources

Farms is not regulated is a further complicating factor for peak loads east of Cos Cob. All of these factors make it impossible to consider the total capacities in Table I when estimating the system loads that can be handled.

One of the most serious problems encountered was that of low voltage at the eastern end of the system during maximum load conditions. With the limitations of the supply sources at this end, the voltage during the peak hour, or with heavy concentrated local loads, would drop as low as 8,000 volts or 73 per cent, even with the voltage at Cos Cob raised to 11.8 kv. This imposed further limitations on the kilowatt capacity of Cos Cob because of the additional reactive that this station had to carry at the higher operating voltage.

By 1942, the heavy traffic due to the war and the acquisition of heavier electric locomotives were clearly indicating the need for power system improvements. Studies were made on the network calculator to determine what could be done to improve voltage conditions with the heavier loads. These studies indicated that some further means were needed to sustain the voltage at the eastern end of the system, particularly by the addition of reactive supply nearer this load center, which would not only reduce transmission losses, but would allow a better use of the Cos Cob kilowatt capacity. These studies further showed that the addition of approximately 10,000 reactive kilovolt amperes at some point east of Bridgeport would provide the desired improvement.

Synchronous Condensers Versus Shunt Capacitors

The first reaction was to augment the existing reactive sources at the eastern end of the electrified section by additional synchronous capacity. However, the extensive use of shunt capacitors on 60-cycle 3-phase systems led to their consideration in this application. Studies[1] reported in 1943 show that when losses are capitalized at $150 per kilowatt shunt capacitors have economic advantages over synchronous condensers for stations up to at least 35,000-kva three-phase, at 13.8-kv and 60-cycles. As the capacitors available for 25-cycle service were standard 60-cycle units derated by a factor of 2.4, there was a general impression that capacitors could not be justified for 25-cycle service. However, synchronous-condenser capacity for single-phase 25-cycle service costs at least 2.25 times the corresponding capacity for a 60-cycle, 3-phase system. Single-phase machines are usually built as 3-phase units with one idle winding, the capacity of the unit being approximately 1.73 times the rated single-phase output. In the range of sizes considered the cost of single-phase capacity is about 1.5 times the cost of 3-phase capacity. In addition, 25-cycle synchronous condensers cost approximately 50 per cent more than 60-cycle units. The 25/60-cycle cost ratios of 2.4 for shunt capacitors and approximately 2.25 for single-phase synchronous condensers indicated that the general economic considerations in the proposed application were comparable to those in 60-cycle 3-phase installations.

A rotating machine would have required the installation of 11/22-kv transformer capacity corresponding to the machine rating because studies showed the reactive source should be connected to the 22-kv trolley feeder system. Considering this factor, the cost of a 10,000 kva synchronous condenser installation, without capitalized losses, would have exceeded the cost of shunt capacitors. In addition, the losses for the synchronous condenser installation were

Figure 3. Typical line voltage at Woodmont before installation of capacitors

at least 350 kw higher than the capacitor station losses.

Other factors also favored a choice of shunt capacitors for the additional reactive source. As the traction system is single-phase, 3-phase power is not available for starting synchronous condensers excepting at the power sources, which meant that rotating machines would have presented a starting problem. It would have been necessary to bring 3-phase power to the synchronous condenser location or to install a single-phase traction motor for starting purposes, both of which meant higher cost. It was also decided that a rotating machine, if used, should have completely automatic features in order to save the cost of three shifts of operators.

The superior voltage regulating characteristics of a rotating machine were considered carefully. However, as the shunt capacitors would operate normally in parallel with regulated machines, it was decided that manually or automatically switched capacitors would give the desired system voltage control. Lagging capacity was not required so this advantage of a synchronous condenser received no consideration. Based on these factors, it was decided that shunt capacitors were the economic solution to the power system problems.

General Characteristics of Capacitor Installation

The network calculator studies showed that 10,000 kva of shunt capacitors distributed along the eastern part of the electrified section would give the desired improvements in system voltage. However, as suitable level land area was available only at Woodmont, midway between Devon and New Haven, it was decided to make the entire installation at this location. Further studies on the calculator

Figure 5. Equivalent circuit of elementary system at harmonic frequency

indicated that the general voltage improvement would be nearly as good with all capacitors located at Woodmont as with the units installed at several locations.

It was recognized that 10,000 kva in reactive connected to the 11-kv trolley-rail circuit would seriously overload the two 2,000-kva balancing transformers at Woodmont. For this reason, it was decided to install the capacitors in two major groups, 5,000 kva across the trolley-rail circuit and 5,000 kva on the feeder-rail circuit. A decision was made to switch the capacitors in 2,500 kva steps in order to limit the voltage change, due to switching, to approximately five per cent. Shipping limitations made it desirable to design the individual outdoor capacitor housings for a maximum of 1,250 kva at 25 cycles. The final station design was, therefore, based on eight individual units of approximately 1,250 kva, each, controlled with four circuit breakers.

The rated voltage of the capacitor station was set at 10.8 kv. This allowed the use of three 3,600-volt capacitor units in series and represented the base voltage, which if increased by 10 per cent (the limit of overvoltage allowable on the capacitors) would not exceed 11.9 kv, the maximum safe operating voltage of the older motive power.

The nature of the voltage fluctuations on the power system (see Figure 3) raised some question relative to the application of automatic voltage control to the capacitor banks. However, as it was deemed essential to have overvoltage relays and timers to remove the capacitors from service in case of sustained overvoltage, it was decided also to install the necessary undervoltage relays and timers required for complete automatic control. The control could then be used in a manner determined by operating experience.

Harmonic Control

A transformer in order to generate a sine wave voltage must draw an exciting current containing harmonic components, the magnitudes of which are a function of the grade of iron in the core and the flux density at operating voltage. Figure 4[3] shows the order of magnitude of these harmonic components for a typical grade of transformer steel. These harmonic currents normally flow between the transformers and the power sources and may cause interference with communication circuits. This factor is particularly important on a single-phase system because no low-impedance path is provided for the third harmonic currents within the transformers, and these currents must flow back to the supply points. As the New York, New Haven, and Hartford Railroad system has over 180,000 kva in station and line transformers, not including transformers on the locomotives and motor cars, it was deemed advisable to give careful study to harmonics and their control in the application of the 10,000 kva in shunt capacitors. A shunt capacitor installation cannot generate harmonics but can cause a redistribution of the harmonic currents in a system, and can increase the harmonic content of the system voltage if resonance exists between the capacitor bank and the power sources and loads. Preliminary calculations indicated a possibility of resonance so it was decided to make a harmonic study on the

network calculator. The method of analysis proposed by Feaster and Harder[3] was used in making the investigation.

In this method, a transformer is represented by an internal voltage and a reactance at each harmonic frequency (see Figure 5). Normally the harmonic reactance of the transformer is large by comparison to the source reactance at harmonic frequency so only a small fraction of the internal harmonic voltage appears at the transformer terminals. With large banks of shunt capacitors, it is possible to have parallel resonance between the capacitor bank and source reactances at a particular harmonic frequency.[4] This harmonic component of the transformer exciting current is then blocked because the system impedance as viewed from the transformer terminals is high, and, in the extreme case, all of the transformer internal harmonic voltage can appear at the transformer terminals.

Transformer internal voltage and reactance data are not generally available and usually must be estimated. Fortunately, in most applications, it is not necessary to know these values accurately, but only to have reasonably correct ratios between the harmonic voltages and reactances. The latter can be estimated from the transformer exciting current and the data in Figure 4. In the study, herein reported, the exciting currents were obtained from the transformer manufacturer, and the third and fifth harmonic components estimated from Figure 4 at 50 and 20 per cent, respectively, of the total exciting current. The transformers were assumed to have internal voltages of 50 and 30 per cent at the third and fifth harmonic frequencies, and the internal reactances adjusted to give the desired harmonic currents on short circuit. These calculations are summarized in Table II. The station and line autotransformers were concentrated at five locations, with operating voltages of 11.5-kv at the major generating stations, and 11-kv at other locations. The equivalent circuit used in the network calculator study is shown in Figure 6 for the third harmonic frequency. The line and source reactances are three times the corresponding 25-cycle values. The source reactances are based on maximum generating conditions; other generating capacities as indicated in Figure 7 were considered. The shunt capacitor kva at Woodmont was varied between 2,500 and 13,000, and the capacitor harmonic current measured for each value. The results of this study are summarized in Figure 7. It will be noted that resonance is indicated by the high-peak currents for certain combinations of capacitor megavolt-amperes and generation. For example, with no machines in service at Devon and Station *A*, the third harmonic current approaches 70 per cent of rated current of the capacitor bank. The harmonic voltage at the capacitor location is for each case one third of the harmonic current, the capacitor bank reactance being equal to 33.3 per cent at the third harmonic. The large harmonic currents predicted were not considered particularly objectionable, but the harmonic voltages, which approach 24 per cent were higher than could be tolerated. A second study was made with the capacitor bank tuned to resonance with a series

reactor, the harmonic current thus obtained being indicated by the dashed curve in Figure 7. The reactor prevents any possibility of resonance between the capacitor bank and the system, and limits the harmonic currents in the capacitors. The reduction in harmonic voltage is considerably greater than the reduction in current because the impedance of the tuned bank is very low, being zero for the case of exact tuning and zero losses.

Figure 8 summarizes a similar study at 125 cycles, the fifth harmonic frequency. Resonance is also indicated at this frequency so additional studies were made with the capacitor installation tuned to resonance. Tuning gives the same large reduction in harmonic currents and voltages as were obtained in the third harmonic studies.

Based on these network calculator studies, it was decided to tune the capacitor installation for both the third and fifth harmonic frequencies. Consideration was given also to varying the capacitor kva with generation conditions to prevent resonance but this was deemed impractical from an operating standpoint. Trouble from the seventh and higher harmonics was not contemplated so tuning for frequencies above the fifth was not provided. Field tests and operating experience have substantiated these conclusions.

As the capacitor installation was to consist of eight banks of approximately 1,250 kva each, tuning was provided for one bank on the trolley-rail circuit and one on the feeder-rail circuit at each of the two frequencies. The individual capacitor units are rated at 15 kva with a 35 per cent margin above this value to allow for over-voltage operation and harmonics.

The units are operated at only 6.25 kva fundamental frequency at 25 cycles so have considerable margin for harmonic currents.

Description of Installation

The arrangement of the equipment included in the station is illustrated in Figures 9 and 10. In these diagrams, 1*CT*, 2*CT*, 3*CT*, and 4*CT* represent the capacitor banks connected to the trolley-rail circuits; and 1*CF*, 2*CF*, 3*CF*, and 4*CF* those connected to the feeder-rail circuits. There are eight racks in all, each of approximately 1,250 kva capacity. In series with banks 1*CT* and 2*CT* are reactors *TX*3 and *TX*5, these being the tuning reactors for the third and fifth harmonics respectively. These reactors are connected to the trolley bus through circuit breaker *TC*1. Similarly, capacitor banks 1*CF* and 2*CF* are in series with reactors *FX*3 and *FX*5, respectively, both reactors being connected to the feeder bus through circuit breaker *FC*1. Capacitor banks 3*CT* and 4*CT* have no

Figure 10. Physical arrangement and designation of equipment

Figure 11. A 1,250-kva capacitor housing

Figure 13. General appearance of capacitor station

tuning reactors and are connected to the trolley bus directly through circuit breaker *TC*2. Similarly, banks 3*CF* and 4*CF* are connected directly to the feeder bus through circuit breaker *FC*2.

The capacitor units are in steel housings approximately 20-feet long 12-feet high, and 4-feet wide. On each side are five doors hinged vertically, which give access to all the capacitor units. The interior of these houses contain three shelves, each insulated from ground and from each other, on which are installed the capacitor units. All the units along one side of the housing on each shelf are in parallel, and the three shelves are in series. The units on the opposite side of the housing are also in parallel on each shelf, with the three shelves in series. Thus, there are two similar groups of capacitors arranged in series-parallel in each housing. These two groups are connected to a single high voltage roof bushing at one end of the housing, while the low voltage connections of the two groups are made to the rail bus through a differential current transformer, Figure 12.

Each capacitor unit is provided with an external 15 ampere fuse, and an internal discharge resistor to decrease the capacitor voltage to a safe working level within five minutes after the unit is de-energized. A discharge coil across each parallel group will drain the units within a few seconds, which minimizes the inrush currents if a bank is re-energized within a short time after its removal from the system.

The entire installation consists of 1,694 15-kva 60-cycle units rated at 6.25 kva at 25 cycles. The number and voltage rating of the units in each housing are listed in Table III. The voltage rating of the tuned banks is higher than the rating of the untuned banks because of the voltage rise produced by the tuning reactors.

The reactors are air-core oil-insulated in cylindrical steel tanks equipped with radiators for self-cooling. The third-harmonic reactors are rated at 156 amperes and have taps for inductances of 70.0, 72.3, 75.0, and 78.2 millihenrys. The fifth-harmonic reactors are rated at 142 amperes, with inductances of 21.4, 21.9, 23.0, and 23.7 millihenrys.

The circuit breakers are 500,000-kva 600-ampere 34.5-kv, type *GO-2S*, equipped with deion grids. The circuit breakers are solenoid operated from the existing 125-volt station battery. Bushing current transformers are provided for differential protection of the busses and overcurrent protection of the reactors, disconnecting switches, and capacitor banks. All protective relays are located in a control cabinet on the outdoor circuit breakers. The manual control switches for operation of the circuit breakers are on the local control switchboard in the adjacent signal tower. Normally these control switches are in the automatic control position, whereby the circuit breakers are operated automatically by master over- and undervoltage relays (mounted on the control switchboard) which operate the individual timing relays in each circuit breaker for tripping or closing.

When the voltage rises above 11.8 kv, the overvoltage relay operates an auxiliary relay which seals itself in and causes all four circuit breaker tripping timing relays to start. These are so timed that *FC*2 circuit breaker opens in 1/2 minute; *TC*2 in 1 minute; *FC*1 in $1^1/_2$ minutes; and *TC*1 in 2 minutes. Should the voltage drop below 11.4-kv during any part of this time sequence, the master

The units on each shelf are in two groups—half on each side.

voltage relay drops back, breaking the seal on its auxiliary relay and all timing relays are reset. If all circuit breakers are open and the voltage drops below 10.8-kv, the undervoltage master relay operates an auxiliary relay which seals in and causes all four circuit breaker closing timing relays to start. These are so timed that *TC*1 circuit breaker closes in 1 minute; *FC*1 in $1^1/_2$ minutes; *TC*2 in $2^1/_2$ minutes; and *FC*2 in 3 minutes. If the voltage rises above 11.3-kv during any part of this time sequence, the master voltage relay will break the seal of its auxiliary relay, and all the timing relays are reset. It will be noted that the tuned groups are taken off the line last, and restored to service first, and that the trolley-rail groups are left in service in preference to similar feeder-rail groups.

Figure 15. Typical trolley-rail voltage wave forms

Control circuit breakers closed:

2—*TC*1 and *FC*2
3—*TC*1, *FC*1 and *TC*2
4—All

Should the differential or overcurrent relays operate to trip a circuit breaker, that circuit breaker is opened and locked out by a "lock-out" relay, and cannot be restored to service from the control switchboard until after maintenance men have reset the lock-out relay at the circuit breaker.

Lightning arresters, type *SV*, 15-kv, are connected to the trolley and feeder busses supplying this equipment. All of the capacitor housings, reactors, and circuit breakers are mounted on concrete pads, raised slightly above the ground, which is covered with fine crushed stone. The busses, disconnecting switches, and lighting fixtures are supported on steel poles and structures. All control wiring is in underground conduit. The yard is entirely enclosed by an eight foot wire mesh fence. Adequate illumination is provided at all equipment for night maintenance.

The entire capacitor station cost was less than $23 per kilovolt-ampere, installed, including all engineering. Figures 13 and 14 show the general appearance of the completed station.

Tests and Operating Results

The station was placed in service on March 14, 1947 and operated experimentally for the next two months to determine proper relay settings and co-ordination with the other reactive supply stations. Very careful and comprehensive tests were made in May to check the tuning of the reactors and to determine the effects on the neighboring communication lines. The tests indicated very conclusively the need for tuning, and proved that the capacitors presented nothing in the nature of an inductive co-ordination problem. Several short circuit tests were made in July, on a trolley-rail circuit near the capacitor station, to determine the effect of the capacitors on the interrupting performance of the line circuit breakers and on the neighboring communication lines. There was no difference found by study of oscillograms of the fault current and the voltage induced in nearby telephone circuits at the time of the fault between the conditions with and without the capacitors connected to the system.

Figure 16. Oscillogram showing circuit breaker performance during charging current interruption

Third and fifth harmonic voltages of 18.4 and 11 per cent respectively, were measured with the tuning reactors short-circuited and with the Woodmont trolley-rail voltage at 11.8-kv. The maximum harmonic voltages recorded with the reactors in service were 1.2 and 0.19 per cent for the third- and fifth-harmonics, respectively. A study of the system voltage with a cathode-ray oscilloscope showed that the phase relations between the fundamental and harmonic frequencies changed with system conditions. Typical trolley-rail voltage wave shapes are illustrated in Figure 15.

Oscillograms were also made of the surges between capacitor groups when one group was switched on and off. As shown by the oscillogram in Figure 16 the circuit breaker interrupts the capacitor current without any evidence of restriking. The contacts of the *FC*2 and *TC*2 circuit breakers were inspected in October after over 2,000 operations. These inspections indicated that the number of operations expected (which will average 10 per day on the *FC*2 and *TC*2 circuit breakers, 5 per day on *FC*1 and an occasional operation of *TC*1) will present no serious maintenance problem.

The capacitor station has successfully fulfilled all expectations by:

1. Raising the trolley-rail voltage on the eastern end of the system by at least 2,000 volts during peak load conditions.

2. Releasing an estimated 6,000 kw of generating capacity at Cos Cob. The cost of this additional capacity is less than $40 per kilowatt, based on the investment cost of the capacitor installation.

3. Reducing the number of hours of operation of the three frequency changers at the eastern end of the system, with a possible saving in losses of at least $20,000 per year.

4. Reducing the transmission system losses by supplying reactive requirements closer to the load centers.

Discussion

R. R. Beisel (Gibbs and Hill, Inc., New York, N. Y.): In so far as the construction of the capacitor substation is concerned, the installation of the oil circuit breakers, reactors, bus structures, metering and protective devices did not present difficulties out of the ordinary.

However, the installation of capacitors presented a special problem due to their unusual size and weight. The capacitor houses were 11 feet 8 inches high, 20 foot long and 4 foot wide, and weighed $5^1/_2$ tons each.

Delivery of the capacitor houses to the site of erection by truck was not possible because of light wooden bridges and unsuitable unimproved country roads. The equipment, therefore, had to be delivered over the railroad's 4-track main line on a flat car to the job site, necessitating the removal of normal railroad traffic from the tracks used. Moreover, insufficient clearance under the signal cables presented a problem in unloading.

Careful study of conditions revealed that it would be possible to place the equipment on the previously prepared foundations by means of a heavy truck crane with a boom of predetermined length. The train positioned the equipment under the boom tip, and a specially prepared cradle was lowered and secured to the capacitor house. The house was lifted clear of the flat car, the car pulled out from under and the house lowered to a point where it would be just clear of the rails, switch rods and miscellaneous cable boxes. The boom was then swung until the tip was brought to the heavy messenger supporting the signal cables overhead. Two men then scaled the boom and raised the cables with their shoulders sufficiently to permit swinging the boom tip underneath the cables. It was then possible to place the capacitor house on its foundation without further interference of the signal cables with the boom of the crane.

In this manner the equipment was unloaded without incident in a relatively short time. In one case when it was imperative to clear the track for traffic, the entire operation was completed in seven minutes.

S. S. Watkins (Gibbs and Hill, Inc., New York, N. Y.): The voltage charts in Figure 3 of the paper give some indication of the problems that were encountered in the control of the capacitors. The automatic control described in the paper was the result of considerable study of the railroad's power distribution system and the expected effect of the capacitors. Some features of that study will be described here.

In order to realize the expected benefits of the installation it was important that, for as great a proportion of the time as possible, the capacitors remain connected and the voltage be held above 10.8 kv. On the other hand, avoidance of injury to either the motive equipment or the capacitors required that the upper limit of sustained voltage be held at 11.9 kv.

Studies on the network analyzer had indicated a voltage improvement of more than 500 volts at Woodmont for each 2,500 kva of capacitors connected at that point, or more than 2,000 volts for the entire 10,000 kva. During predictable periods of light load, scheduled shut-down of frequency changer sets was expected to offset much of the voltage rise caused by the capacitors, so that the average voltage would be within desired limits. Reduction in hours of operation of frequency changer sets was one of the main objects of the capacitor installation. But the pattern of frequent and severe voltage changes caused by train operation would remain. It was apparent that capacitor switching would be necessary. As all circuit-breaker operations at Woodmont are performed by a signal tower operator on telephone orders from the power director, manual control alone would not have been practical.

Quick response control comparable to that of a feeder voltage regulator would have cut the capacitors in and out much more frequently than was either necessary or desirable, and would have required contactors for this switching service. It was not necessary that the voltage be smoothed out but only that it be held within the stated limits. As fault protection required the installation of circuit breakers of 500,000 kva interrupting rating, economy dictated that these be used for all switching if possible.

Automatic control using an overvoltage relay, an undervoltage relay, and auxiliary timing relays, as described under the heading "Description of Installation" of the paper, was finally adopted. This method would avoid operation on momentary swings and would be sufficiently flexible to permit adjustment of settings as indicated by operating experience. The decision to switch in banks of about 2,500 kva, causing voltage changes between 500 and 600 volts, gave assurance that hunting could be avoided, as the spread between the proposed upper and lower voltage limits was about 1,000 volts.

The decision to use the circuit breakers for voltage-control switching emphasized the importance of keeping switching operations to a minimum. Studies were made to estimate the performance of the proposed automatic control, while consideration was still being given to the installation of a 2,500-kva bank at each of four locations. Voltage charts from each location were studied through an 8-hour period of a typical day. Suitable adjustments of these charts were made for the effect of frequency changers that would be shut down and for the effect of cutting capacitor banks in and out. Several trial values of voltage and time were used before the number of circuit breaker operations was satisfactorily reduced. The study nearest to the conditions of the final installation used undervoltage settings of 10.3 kv with $2^1/_2$ minutes delay and overvoltage settings of 11.8 kv with 5 minutes delay. This study indicated that the circuit breaker at Woodmont would operate about 10 times in 24 hours, those at the other points less frequently. It indicated maximum swings of 12.25 kv or less and average voltages of 12 kv or less while the capacitors were on. These results gave promise of satisfactory performance of the proposed automatic control, as the opinion had been obtained that the circuit breakers could stand 35 operations per day without excessive annual maintenance.

After decision had been made to locate the entire 10,000 kva of capacitors at Woodmont, consideration was given to automatic sequencing such as to equalize the numbers of operations of the several circuit breakers. However, it was decided that sequence control by the settings of the timing relays for each circuit breaker would be more suitable. The desirable sequence was governed by two considerations, first that tuned banks be in service whenever any capacitors were connected, and second that the trolley-rail banks be in service first and out last in preference to similar feeder-rail banks. These considerations established the sequence described under the heading "Description of Installation" of the paper, which necessarily would produce differences in the numbers of circuit breaker operations. The expected differences were accepted, as it appeared that the number of operations on any one circuit breaker would not be excessive.

The method of estimating performance of automatic control will be described here, using for simplicity the actual installation of the four 2,500 kva banks at Woodmont. The Woodmont trolley-rail voltage chart for a typical day before the capacitor installation was used for the study. At the starting time on the chart all capacitors were assumed as connected. Frequency changers were assumed to be taken off as load conditions permitted. Previous studies on the network analyzer had shown the net effect of these switching operations, in terms of net volts added to or subtracted from trolley-rail volts at Woodmont. Adjustment was made, not by redrawing the voltage graph, but by moving the voltage scale in the direction opposite to that of each voltage adjustment. A duplicate of the voltage chart scale was drawn at the left hand edge of a piece of cardboard and the upper and lower voltage relay settings were marked conspicuously. This sliding scale was placed at the starting time on the voltage chart and

moved vertically by the amount of the net adjustment required, and then was moved horizontally in the direction of time. When the voltage graph rose above the upper setting on the sliding scale the first timing relay was assumed to start. When the graph had remained above the setting for a time equal to the setting of the first timer, the first 2,500-kva bank of capacitors was assumed cut out and the sliding scale was raised 500 volts. If the graph was still above the upper setting, time continued to be counted for the timer of next longer setting until either the next 2,500-kva bank was cut out or the voltage graph dropped below the setting on the sliding scale. Whenever the voltage graph dropped below the lower setting the converse of the foregoing procedure was followed. As long as the graph remained between upper and lower settings the capacitors were assumed to remain unchanged. Records were made of each operation in or out and the results presented in graphic form.

In the studies that actually were made, voltage charts for each of four locations were used and voltage adjustments by sliding scales were made at each location whenever switching occurred at any one of them. The studies of expected performance of automatic control were used as guides in determining the voltage and time settings that were applied before the trial operation on March 14, 1947.

On March 14 and 17 graphic voltage charts and observations of current, voltage, and circuit breaker operations were made. The number of circuit breaker operations was even less than anticipated, while duration and extent of uncorrected voltage changes indicated need for more frequent operation. During periods of uncorrected swings of overvoltage the readings of current through the tuned banks showed a marked increase beyond the values attributable to 25-cycle admittance. This obviously resulted from increase in the harmonic components as transformers on the system became overexcited by the higher voltage. This explanation was corroborated by the increasing distortion observed on the oscilloscope screen.

Accordingly the time settings were shortened. After further observation of results the settings recorded under the heading "Description of Installation" of the paper were established as satisfactory. In conclusion it may be remarked that the voltage relays for automatic control for this application require relatively narrow bands between pickup and dropout. Bands much wider than the 4 and 5 volts previously stated, would make the control more sensitive to momentary swings and might decrease the effective band between the overvoltage relay and the undervoltage relay to the point where pumping would occur.

H. F. Brown: The discussions by Watkins and Beisel amplify some of the special engineering and construction problems encountered in the design and erection of this capacitor installation.

In conclusion it may be stated that this capacitor installation has proved to be a very satisfactory and economic solution of the various problems with which the railroad was confronted: low voltage at the eastern end of the system; and concentration of reactive on the central and eastern power supply points, which limited the potential output of the central supply station generators.

Unusual Performance of Standard 230-Kv Impulse and Tank-Type Oil Circuit Breakers on Field Tests

E. B. RIETZ
ASSOCIATE AIEE

Synopsis: The requirements of the United States Bureau of Reclamation for 230-kv circuit breakers at Grand Coulee Dam which would far exceed present-day standard circuit-breaker ratings, required field tests to check the performance of standard circuit breakers in order to predict the required designs for higher ratings. Standard 3,500 megavolt-amperes (mva) low oil content impulse- and tank-type oil circuit breakers were tested on the maximum capacity available of over 7,000 mva. Usually satisfactory performance was observed under all test conditions indicating that standard circuit breakers of these types incorporating modern methods of arc interruption, will require but little change to adapt them to the Grand Coulee Dam requirements for ratings of 10,000 mva.

EARLY LAST YEAR, power circuit breaker engineers were told by the Bureau of Reclamation that the requirements of 230-kv circuit breakers for Grand Coulee Dam, would involve circuit breakers for duties of approximately 10,000 mva. This was a conclusion that had been reached after a comprehensive design and network analyzer study to determine the most desirable bussing arrangement for the Grand Coulee Power Plant and to avoid the use of 230-kv current limiting bus tie reactors. At that time, the maximum standard 230-kv circuit-breaker rating was 3,500 mva. Although factory tests of new interrupters had indicated that 5,000-mva circuit breakers were feasible,[1] no work had been done to design them because of lack of demand. The thought of a circuit breaker of twice that rating was certainly one to trick the imagination. However, it was soon realized that the higher rated circuit breaker presented the best over-all approach to the problem and consideration was given to arriving at a satisfactory solution. The agreement of the Bureau of Reclamation that such a solution could be expedited by providing facilities for field tests at Grand Coulee Dam Power Plant lead to the program that is being described in this and companion papers.

Consideration of Existing Circuit Breaker Designs

The General Electric Company had two designs of circuit breakers which could be considered. The first was represented by the low oil content impulse-type circuit breaker, and the second, by the conventional tank-type circuit breaker with multibreak interrupters.

Impulse-Type Circuit Breaker

The impulse circuit breakers had an outstanding record. The basic design was created in the early 1930's for 3-cycle 287.5-kv circuit breakers for the Boulder Dam lines.[2] The first of these circuit breakers went into service in 1934. At the same time, 138-kv circuit breakers of similar design were installed at the Los Angeles end. Five years later, additional circuit breakers of both ratings were installed. About the same time, 230-kv circuit breakers were designed and built for the Pacific Northwest. At the present time, approximately 50 impulse circuit breakers are in service. Their record has been exceptionally satisfactory. Interrupting performance has been unquestioned. They have demonstrated a very desirable interrupting characteristic on line charging currents where interruption is positive and restriking is unknown. Interrupting times are within 3 cycles from 0 to 100 per cent of rating. Operating experience has also been very satisfactory. Maintenance has been reduced because a minimum quantity of oil is subject to deterioration from arcing.

The performance to be expected on the higher duty could be extrapolated from two sources: (1) the exceptionally satisfactory field record of fault interruptions and (2) factory tests. Although designs had been built for 3,500 mva at 287.5 kv and for both 3,500 and 4,000 mva at 230 kv, the majority of the 230 kv experience centered around 2,500-mva rated circuit breakers on the system of the Bonneville Power Administration. Two of the 3,500-mva 230-kv rated circuit breakers had been in service at Grand Coulee Dam for about two years. The pertinent observations from field experiences centered around the excellent condition of the oil and contacts after numerous interruptions leading to the conclusion that they had been accomplished easily and with little generation of arc energy. Factory tests gave no indication of approaching the limits of capacity. On these bases, the impulse circuit breaker appeared to have a large margin of reserve and was certainly worthy of further consideration.

Tank-Type Circuit Breaker

The modern tank-type circuit breaker represents a product of years of evolution that in itself bespeaks a series of improve-

Paper 48-41, recommended by the AIEE switchgear committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26-30, 1948. Manuscript submitted November 19, 1947; made available for printing December 9, 1947.

E. N. Rietz is with the power circuit breaker division of the General Electric Company, Philadelphia, Pa.

The author speaking for the General Electric Company would like to take this opportunity to congratulate the United States Bureau of Reclamation and its engineers on their progressive attitude which has made possible these field tests so that circuit breakers best suited to their requirements can be developed. Acknowledgement is also made of the interested co-operation of the Bonneville Power Administration in arranging for these tests to be made on their power system so that maximum fault conditions could be obtained.

Figure 1. Cross-section of a pole of the 230-kv low-oil-content impulse circuit breaker showing the oil piston which moves oil between stationary and movable contacts on opening

Figure 2 (right). Cross-section of a pole unit of the 230-kv tank-type circuit breaker showing relationship of component parts

ments that ought to reflect in a capacity beyond its rating. Each new interrupter, although usually created to take care of a specific condition on which its predecessor failed, had more capacity to handle the higher duties. Recent requirements for higher speed clearing and reduced oil deterioration resulted in interrupters having such short arc durations that pressures and other mechanical stresses were automatically reduced. Modern 3-cycle interrupters, therefore, had improved interrupting capacity because they had to interrupt in such a short time. As a result, they could be expected to have capacities beyond their tested ratings. These characteristics were present in the type *FK-439* oil-blast circuit breaker with its improved multibreak interrupters and pole unit structures.[3]

As with the impulse circuit breaker, an estimate of the tank-type circuit breaker performance on higher capacities had to be based on field experience and factory test data. Field experience covered both 230 and 138-kv multibreak interrupters in considerable numbers and rated up to 3,500 mva. Field tests had been made on both voltage ratings, the most recent series having been made in 1944 on a 3-cycle 3,500-mva 138-kv circuit breaker.[4] This proved an excellent performer and could be used as a yardstick for a 230-kv circuit breaker with similar type interrupters. Factory tests were even more complete than on the impulse circuit breaker, because unit interrupter testing was possible with the resistance voltage grading that was used across the interrupters of a pole unit. These tests indicated that the tank-type circuit breaker with modern multibreak interrupters also had an appreciable margin over assigned ratings.[3]

The Test Circuit Breakers

With two standard circuit breakers available for the new requirements, a test program was arranged to include both of them. Fortunately, it was possible to use the impulse circuit breaker already installed in the yard for one series. The second series was made on a new standard tank-type circuit breaker ordered by the Bureau of Reclamation and being shipped to the Shasta Project in California. Before being sent to Shasta, it was, therefore, routed to Coulee Dam for the field tests.

The impulse circuit breaker was a type *FG-25*, rated 3,500 mva 230-kv, 800-amperes with 3-cycle interrupting time. Figure 1 shows a cross-sectional view of a pole unit. As contrasted with other conventional oil circuit breakers, at interruption oil is forced to flow between the movable and stationary contacts by the movement of a mechanically operated piston. The circuit breaker consists of a horizontal interrupting unit with contacts and actuating linkage, a vertical column which encloses an insulated operating rod connecting the operating mechanism and the contact actuating linkage, an insulator column, and a spring charged operating mechanism. Springs in the operating mechanism are charged so that their energy is transferred to the oil piston and contacts for interruption and opening of the circuit breaker. This guarantees a positive oil flow which gives the same interrupting times from 0 to 100 per cent of rating and is particularly advantageous when interrupting line charging currents where restriking is eliminated and dangerous overvoltages prevented.

The tank-type circuit breaker was a

Figure 3. Cross-section of the 230-kv multibreak interrupter. Resistor unit for grading voltage and helping in interruption of capacitance current is connected between top adapter and lower stationary contact

type *FK-439*, rated 3,500 mva 230/196-kv 800-amperes with 3-cycle interrupting and 20-cycle reclosing times. This was a standard circuit breaker in current production. Figure 2 shows a cross-sectional view of a pole unit and Figure 3 a view of the multibreak interrupter. The general features were described before the AIEE two years ago.[3] This circuit breaker had 78-inch diameter pole unit tanks, an insulation level of 425-kv 60-cycle, and 900-kv impulse, improved multibreak interrupters, high speed pole unit mechanism linkages, and an air operator.

Test Program

Field tests were made on the two circuit breakers on the weekends of March 23 and April 6, 1947. A full description of the test setup and test results is contained in a paper presented by C. L. Killgore and W. H. Clagett.[5]

Reclosing tests were not made on the type *FG-25* impulse circuit breaker as it was equipped with a spring charged operating mechanism which is not arranged for ultra-high speed 20-cycle reclosing. A recently developed air operator for ultra-high speed reclosing of impulse-type circuit breakers was unfortunately not available at the time of these tests.[6]

Laboratory recording devices were installed to obtain as much related information as possible. These included: travel indicators for lift rod movement, recorders for measuring pressures in the multibreak interrupters, tank pressures below and above oil level and pressures in the interrupting unit of the impulse circuit breaker and strain gauges for mounting on the tank supports of the tank-type circuit breaker.

Test Results

The circuit-breaker performances were without exception unusually satisfactory.

The impulse circuit breaker performed as expected on the line dropping tests and there were no restrikes and no indications of switching overvoltages. The average arcing time was less than one-half cycle. Although the test schedule did not include line conditions above 260 miles in length, previous experience confirmed by these tests would indicate the same satisfactory performance on longer line lengths.

The series of 14 fault operations on the impulse circuit breaker left the contacts in serviceable condition and did not greatly affect the dielectric strength of the insulating oil. There was little vibration of the circuit breaker and no ground shock. The interrupting times are shown by Figure 4 and average 2.8 cycles. More recent designs of operating mechanisms would have faster mechanical unlatching times and would reduce these times by almost one-half cycle.

The tank-type circuit breaker had no difficulty in switching 382 miles of line, or the equivalent of 28,500 charging kva. No restrikes were obtained on the 100 and 200-mile lengths. A single restrike occurred on about 60 per cent of 300 and 382-mile tests, but the resistor unit of the multibreak interrupters limited the overvoltage to a safe value. The cathode ray oscillograph records showed nothing over 1.9 times normal. The resistor currents were interrupted in less than half the stroke of 28 inches.

The fault tests on the tank-type circuit breaker were without incident. After the first series of 14 tests, the contacts were in condition to perform a considerable number of additional interruptions, but because of the large number of tests proposed for the second series, it was considered desirable to change them.

The reclosing tests included in the second series were remarkable in that there was no visual distinction between the first and second operations of the cycle. For the last four reclosing cycles at maximum duty, modifications were made to the operating mechanism to reduce the time and these were made with 12 cycle reclosing time from trip impulse to remaking of the circuit. These tests demonstrated the interrupting ability of the multibreak interrupters on successive operations with very short time intervals. Admittedly, the duration of resistor current would have to be reduced to make 12 cycle reclosing practical but the tests indicate that the basic interrupter is available and it is believed that the reresistor problem has a fairly simple solution. The interrupting times of all tests are shown by Figure 5. On this circuit breaker also, the disturbance and ground shock were negligible.

Conclusions

The demonstrated performance of these circuit breakers on field tests, lead to the following conclusions:

1. The interrupting performances of both the impulse and tank-type circuit breakers were quite remarkable when it is considered that as standard circuit breakers they interrupted nearly twice their rating with no evidence of distress and no signs that they had reached their limits.

2. Line charging currents can best be interrupted by oil circuit breakers of the im-

Figure 4. Interrupting performance of the 3-cycle 230-kv impulse circuit breaker on field tests showing circuit breaker interrupting times at various duties

Figure 5. Interrupting performance of the 3-cycle 230-kv tank-type circuit breaker on field tests showing circuit breaker interrupting times at various duties

pulse type. However, conventional multi-break interrupters can be combined with suitable resistors to give perfectly satisfactory performance.

3. Ultra-high speed reclosing with reclosing times as low as 12 cycles, is possible at 230 kv and the higher interrupting ratings.

4. Based on these field tests, it is apparent that ratings of 7,500 mva at this voltage can easily be obtained and it is evident to design engineers that only slight changes would be necessary to obtain 10,000-mva circuit breakers.

5. Field tests are a requisite to the development and proof of rating of circuit breakers above 3,500 mva because it does not seem practical to have manufacturers' test facilities large enough to handle these super-ratings.

6. It should not be inferred from these tests that all circuit breakers will perform satisfactorily so much above their rating. There are too many factors involved in the interrupting characteristics of a circuit breaker to draw any such general conclusion.

Discussion

A. W. Hill (Westinghouse Electric Corporation, East Pittsburgh, Pa.): Rietz has given us a good description of two types of circuit breaker construction tested at Grand Coulee recently, and the reader will naturally compare their design and operating problems, and interrupting performance, so as to conclude which will be preferred in this field of high-capacity circuit breakers. The actual test results and contemplated future ratings represent a big step beyond recent standards of 3,500,000-kva maximum.

While describing the tank-type circuit breaker, Rietz states that modern 3-cycle interrupters have increased interrupting capacity because they have to interrupt in such a short time. It would seem a little illogical to assume that interrupting ability automatically rises as interrupting time decreases, for difficulties such as shock pressure surges might actually increase, and I wonder if Rietz is not referring to the naturally higher value of short circuit current which must be interrupted early in the decrement curve.

The reader is left with an unanswered question with the statement that the resistor paralleling the interrupter constitutes a problem which has a fairly simple solution. What is the nature of this solution—to eliminate the resistor completely?

Referring to the impulse circuit breaker, the statement that maintenance has been reduced because a minimum quantity of oil is subject to deterioration from arcing, is understandable so far as time required for filtering is concerned, but the same kind of equipment is required as for tank-type circuit breakers, and in the long run it would appear that more frequent treatment would be inevitable with the relatively higher concentration of carbon.

It would be interesting to know the magnitude of pressures shown on the oscillograms but not identified in the papers, as the mechanical structure using large porcelain units frequently arouses fear of breakage under shock stresses.

It is generally recognized that increased interrupting ability may require only moderate design changes when starting from low ratings, but as we approach short circuit currents of the order of 25,000 amperes, it is not so apparent what steps the designer would take in making the "slight changes" referred to in conclusion number 4. Could these be in the direction of stronger operating mechanisms, greater oil piston output, and so forth, and if so, does this not imply greater and unproved stresses on a porcelain structure which might tend to throw the balance toward the tank type as the preferred choice?

Robert H. Nau and **Frank Fry** (University of Illinois, Urbana, Ill.): The performance of the indicated standard 230-kv impulse and tank-type circuit breakers using the general impulse interruption features have performed exceptionally well in the light of their ratings. However, it seems a foregone conclusion that the manufacturer was aware of the inherent interrupting ability of these designs; otherwise such high power tests would not have been conducted.

For the self-generated pressure interrupter in a steel tank, there is evidence from all sources that with proper design the inherent pressure and flow requirements for almost any interruption can be met. There might be some question in this particular design whether or not the voltage interrupting ability is being used effectively.

With the impulse circuit breaker, the requirements on the piston which produces the pressure for oil flow will naturally be raised for the higher kilovolt-ampere duty so that a reasonable increase in driving force can be expected.

Since a circuit breaker which is sold to interrupt 3,500,000 kva is never called upon to interrupt more than that amount, any interrupting ability above the rating, especially of the orders of magnitude which are evident here, is either purely a gift from the manufacturer to the customer or an inability to design within reasonable limits because of lack of adequate test facilities.

P. L. Taylor (Allis-Chalmers Manufacturing Company, Boston, Mass.): I want to compliment the author on his work in outlining such a marked extension of the range of interrupting capacity of power circuit breakers in the transmission class.

The effect, of tripling the interrupting capacities at the higher transmission voltages, upon power system design seems almost certain to be far reaching.

It is peculiarly fitting that these tests indicating the feasibility of oil circuit breakers up to 10,000,000 kva were made in 1947, the fiftieth anniversary year of the first oil circuit breaker, which was designed by Doctor Leonard Elden in 1897. That these fiftieth anniversary oil circuit breakers are pneumatically operated and that some of the earliest designs of the Elden oil circuit breaker were also pneumatically operated, is worthy of note.

The comments of the author with regard to oil circuit breakers seem to me to be quite significant. He has said in part:

> "The modern tank type circuit breaker represents a product of years of evolution that in itself bespeaks a series of improvements that ought to reflect in capacity beyond its rating."

It has been our experience also, that the oil circuit breaker has a way of coming through.

Again I want to compliment the author on his most important contribution.

E. B. Rietz: For a good many years circuit breaker manufacturers have tried to incorporate in their designs margins of safety to take care of the many unknown conditions involved in the problem of circuit interruption. It does not seem that this is any time to depart from such a desirable practice and, therefore, I can only say to Nau that we will continue to make circuit breakers as good as we can and if large margins of safety result we are glad to pass them on to the users.

It is true that increased laboratory test facilities take more of the unknowns out of circuit breaker performance, but there are still enough left to justify a conservative approach.

Taylor confirms the fact evident to both user and manufacturer of the very great evolution of circuit breaker designs.

The answers to Hill's questions are based on the general design characteristics of the impulse circuit breaker. The porcelain shells which are first evident to the observers are only for weather protection. All loadings during operation are taken by heavy-walled, paper-wound tubes inside of the porcelain shells. The porcelains are not rigidly attached so they can move or vibrate at their own frequency. The maintenance advantages of impulse-type low-oil content circuit breakers can best be answered by the users. They have told us that the reduced quantities of oil necessary to handle during maintenance and the simpler oil facilities required for these circuit breakers are major considerations in their desire to see such circuit breaker designs promoted. These field tests were made primarily to obtain information.

The conclusions relative to changing these circuit breaker designs for still higher ratings were not made with all of the answers at hand.

Field Tests for Development of 10,000,000-Kva 230-Kv Oil Circuit Breakers for Grand Coulee Power Plant

C. L. KILLGORE
MEMBER AIEE

W. H. CLAGETT
MEMBER AIEE

THIS PAPER discusses the field tests which were made on four types of 230-kv 3-cycle oil circuit breakers at Grand Coulee power plant at Coulee Dam, Wash. Faults of over 7,000,000 kva, far exceeding any previous field tests[1-7], were successfully interrupted on the 230-kv system.

These field tests were necessitated by an urgent requirement for the early design and development of 230-kv 3-cycle oil circuit breakers with an interrupting capacity of 10,000,000 kva, rated on a duty cycle of one 20-cycle reclosure, for installation at the Grand Coulee power plant. This unparalleled interrupting capacity is nearly three times that of the 3,500,000 kva circuit breakers which were the largest available up to the time of these tests.

Grand Coulee power plant is the largest hydroelectric power plant in the world and is situated on the Columbia River approximately 90 miles to the west of the city of Spokane, near the center of the state of Washington. The power plant is located near the electrical center of a vast transmission network extending over the states of Washington, Oregon, Idaho, Montana, and Utah. This network is represented by the Northwest Power Pool, with a present total connected peaking capability of approximately 3,500,000 kw. The Northwest Power Pool comprises an interconnection of all major operating utilities of the Pacific northwest as shown schematically in Figure 1, as well as many smaller organizations not shown, and was originated during the recent war emergency for purposes of mutual benefit through pooling of available reserves, taking advantage of load diversity over the two time zones involved, and taking advantage of the diversity of stream flows of the various watersheds in the area. The Grand Coulee power plant, designed, constructed, and operated by the United States Bureau of Reclamation, is connected to the power pool through the transmission facilities of the Bonneville Power Administration.

Grand Coulee Power Plant

Grand Coulee consists of two similar power plants on either side of the river as illustrated in Figure 2. Each power plant will ultimately contain nine of the world's largest hydro-generators each having a nameplate rating of 108,000 kw and an actual peaking capability of 130,000 kw, or a combined maximum in excess of 2,300,000 kw. The Grand Coulee pumping plant, located adjacent to the dam, will ultimately contain twelve 65,000-horsepower irrigation pump motors. The unprecedented size of the ultimate installation, representing a tremendous concentration of short-circuit capacity never heretofore combined in any one place, introduces many unique problems in circuit breaker application, while retaining necessary switching simplicity and flexibility. A unit-system wherein all bussing is accomplished on the high-voltage side of the transformer banks at the 230-kv switchyards is used at Grand Coulee. The installation at Grand Coulee at the time of the tests consisted of only six of the ultimate 18 generating units and the degree of solid bussing, without the use of current-limiting 230-kv reactors, was already limited by the 3,500,000-kva interrupting capacity of the installed 230-kv circuit breakers. The present circuit breaker limitation also dictates the temporary use of a split bus with interleaved transmission lines, illustrated by Figure 3, which also constituted the switching arrangement used during the staged interrupting-capacity tests. Synchronizing power flows between the two bus sections through the three pairs of lines with line impedance acting to reduce circuit breaker duty to below nominal equipment ratings. This split bus with interleaved lines presents a number of undesirable operating difficulties, particularly during switchgear maintenance, and is considered as an interim arrangement only.

Ultimate Bussing Scheme and Circuit Breaker Rating

Comprehensive design and network analyzer studies of system transient stability and circuit breaker duties to determine the optimum bussing arrangement for the fully developed Grand Coulee power plant, have been conducted jointly by the Bonneville Power Administration and the Bureau of Reclamation. These studies involved a great number of schemes including interleaved lines, isolated groups of lines and units, 3-winding transformer banks and 230-kv reactors for bus-ties, and others. The results of these studies will be presented in future

Paper 48-42, recommended by the AIEE switchgear and transmission and distribution committees and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26-30, 1948. Manuscript submitted November 17, 1947; made available for printing December 29, 1947.

C. L. KILLGORE is an electrical engineer with the United States Bureau of Reclamation, Denver, Colo., and W. H. CLAGETT is an electrical engineer with the Bureau at Coulee Dam, Wash.

The authors wish to acknowledge the fine co-operation of the Bonneville Power Administration in arranging for these tests to be made on its power system and on the interconnected system of the Northwest Power Pool. We also wish to acknowledge the fine co-operation of the Westinghouse Electric Corporation and the General Electric Company in making these tests possible. It was only through the efforts of all participants in these field tests that it was possible to obtain such successful results. The undertaking of such unprecedented field tests is a tribute to the courage and vision of the engineering profession.

papers. A 230-kv 5-section ring bus, each section capable of being isolated from the ring by sectionalizing bus-tie circuit breakers was finally selected as the most desirable because of its simplicity and operating flexibility. The ultimate ring-bus arrangement is shown in Figures 4 and 5.

However, this engineering solution was not without its practical limitations. The possible magnitude of asymmetrical short-circuit currents on such a bussing arrangement, with all generators and pump motors in operation, all transmission lines in service and all transformer neutrals solidly grounded, will approach 15,000,000 kva, assuming a circuit breaker contact-parting time of 2.25 cycles after inception of the fault and 1.35 as the system current decrement factor for a totally offset fault. In order to reduce this excessively high circuit breaker duty to a more reasonable value of slightly over 10,000,000 kva, for faults immediately adjacent to the station, certain features will be incorporated into the future station design, such as provision for the installation of transformer neutral reactors. Also, the irrigation pump motors and their associated generators may be operated independent of the 230-kv system. Ten million kva was arbitrarily chosen since it represented the lower limit in the reduction of maximum possible short-circuit currents without resorting to costly 230-kv 500-ampere, continuous rating, current-limiting bus-tie reactors. Emergency line loadings under certain abnormal conditions, required circuit breakers with a 1,000-ampere continuous current rating. A further requirement was that the circuit breakers should be capable of one 20-cycle reclosure with no de-rating factor. The development of such 10,000,000-kva breakers in one step from the presently available 3,500,000-kva designs, obviously required extensive high-capacity laboratory and field tests, the latter at full system voltage, under system conditions, out and beyond the frontiers established at the Philo plant of the American Gas and Electric Company in 1944, and at Grand Coulee in 1945 which were reported previously in earlier papers.[1,2,3,7] As the Grand Coulee power plant on the Northwest Power Pool is the only location where such a tremendous concentration of short-circuit capacity is available, and further, since this system is the only presently known customer for such high-capacity equipment, the Grand Coulee switchyard was the obvious location for the required developmental field tests.

Objectives of Tests

The immediate and specific objectives of the field tests were:

1. To supplement and extrapolate laboratory tests on present designs to higher values of fault currents under system conditions, at full system voltage, and at system rates-of-rise of recovery voltages.

2. To determine the amount of mechanical distress suffered, if any, and other pertinent operating data during the interruption of ultra-high-capacity faults, with the view of detecting and improving any apparent weaknesses or short-comings in the equipment design.

3. To determine, if possible, the actual maximum interrupting rating of the designs being tested, under standard duty-cycle and high-speed 20-cycle or less reclosing conditions on both solid and arcing faults.

4. To determine the behavior and pertinent operating data of several types of interruptor units, with and without shunting resistors, when switching long unloaded transmission lines.

An analysis of these line-switching and high-capacity interrupting duty field tests will permit the manufacturers to extend their present circuit breaker designs, which are described in two companion papers,[13,14] up to the desired 10,000,000-kva level with an infinitely greater degree of certainty and confidence than would have otherwise been possible without the

Figure 1. Simplified schematic diagram of the Northwest Power Pool. Note test circuit breaker location near the electrical center of the system

Figure 2. Grand Coulee Dam and power plants

benefit of field tests, even though the available testing capacity at this time was considerably short of the ultimate goal. One of the most valuable features of any series of field tests, particularly in the field of high-voltage switching, is in substantiating the results of previous laboratory tests, as it is economically impossible to exactly duplicate all field conditions and obtain the necessary short-circuit capacity in the laboratory at full system voltage. Adequate field tests of new equipment almost invariably result in improved designs and the elimination of weaknesses thus resulting in reduced operation and maintenance costs throughout the life of the equipment.

Station Switching Arrangement and Faults

In regard to the fault tests, it was desired that maximum system capacity be reached in several incremental steps on successive tests, rather than subject the circuit breaker to high fault currents immediately. The basic plan for this was to use one or two isolated units (500 to 1,000 megavolt-amperes) for the initial low-current tests; followed by various other incremental steps, such as one bus with three lines and two, three, or four connected generators; or both busses paralleled, with all six lines and either four, five, or six connected generators. Practically any combination was available providing all lines remained in service; not more than two machines were unloaded simultaneously; and not more than four machines were placed on either bus at any one time. In this manner almost any value of fault current could be obtained as desired, involving only a minor amount of station switching to accomplish a change from one fault current to the next.

All faults were single-line-to-ground on *A*-phase only, which greatly simplified the test connections and the otherwise lengthy and involved test program which extended through six weeks, exclusive of the time required for equipment erection and disassembly. During this time a total of 287 test oscillograms were obtained, in addition to the large number taken during preliminary checking and timing of the four circuit breakers involved.

Aside from simplicity reasons, single-phase tests produced about 30 per cent higher fault current than 3-phase tests, with all transformer neutrals solidly grounded to the plant ground mat. All faults were applied directly to the switchyard ground mat, and as these two mats are solidly connected through a counterpoise of several parallel runs of 500- and 750-thousand-circular-mils buried copper cables, this continuously unbroken metallic path provided an extremely low zero-sequence impedance from the point of fault back to the transformer neutrals. This arrangement was largely responsible for the very high values of fault current which were obtained during the course of the tests, as well as the fact that the generator direct-axis, subtransient reactance is only 16 per cent for the Coulee generators.

Pretripping of the test circuit breakers was used extensively during the tests, particularly the high-capacity operations, to take advantage of the rapid current decrement due to the effect of subtransient reactance during the first one or two cycles of fault current. Positive pretripping was accomplished in all cases through a specially mounted "*a*" switch on the main pull-rod above the circuit breaker operating mechanism. In the case of the "open" operations, where the test circuit breaker starts from the closed position, the pretrip switch was mounted on the pull-rod of the adjacent station circuit breaker applying the fault. Pretripping also reduced the shock to the system during high-current tests, to the point, in fact, where the system dispatcher in several instances could not determine by observation just when the fault had been applied. This refers to the few cases where the circuit breaker was pretripped and the fault cleared in 1/2 to 1 cycle. Approximately 15 per cent was added to the circuit breaker duty over similar tests which were not pretripped.

Effect of Tests on System Equipment

Any effect on installed station and system equipment, occasioned by the high-capacity staged fault tests, was considered to be appreciably less than is

Figure 3. Simplified schematic diagram to indicate the normal method of busing the present six units with six interleaved 230-kv transmission lines, to reduce circuit breaker duty to within the present nominal circuit breaker ratings

Figure 4. Ultimate Coulee 230-kv ring bus. Physical arrangement

usually encountered during the general run of ordinary line faults in a storm, for the following reasons:

1. The faults were not accompanied by overvoltage transients which are usually involved with faults of lightning origin.

2. The circuit breaker was purposely pretripped about 1 to $1^1/_2$ cycles fast on the higher-capacity faults, thus reducing the duration of the mechanical stresses within the equipment to as much as one-half that usually encountered under normal fault clearing time. This also permitted a closer setting of the backup relays, reduced the shock to the system, reduced the possibility of a false relay operation at other points on the system, and most important, in case the fault was cleared by backup protection the reduced relay time increased the relative margin of safety in system transient stability.

Assumption (1) was confirmed by magnetic oscillograms obtained of the generator voltages at the machine terminals, revealing the complete absence of transient overvoltages during fault applications. Assumption (2) was confirmed by statements from the system dispatchers to the effect that the faults were of such short duration on the pretripped tests that they had difficulty in observing exactly when they were applied.

Aside from the fact that staged faults involve considerably less hazard to the system than the usual lightning induced line faults, it should also be pointed out that at no time during the extensive series of tests was any permanent station equipment subjected to stresses or operating conditions beyond that for which it was designed. The design specifications for the Coulee generators, for instance, required that the machines be so constructed as to successfully withstand short-circuit stresses incidental to a fault at the machine terminals, at 110 per cent normal voltage. One Coulee generator has been so tested at 100 per cent voltage, and a very detailed inspection of the end turns thereafter failed to reveal a single loosened coil, wedge or support. In the case of the reference circuit-breaker tests in the left switchyard, a transformer bank of 10.8 per cent impedance and nearly a mile of transmission line is interposed between the machine terminals and the point of fault, thereby substantially cushioning the shock on the machine.

A direct comparison of the actual test values of the symmetrical component of short-circuit current obtained during the circuit-breaker fault tests involving a single isolated generator, referred to the low side of the transformer bank, with similar short-circuit currents obtained at the machine terminals during the generator acceptance tests of 1945, indicates that the presence of the transformer bank and line in the circuit reduces the short-circuit current in the machine by a ratio of 0.41 to 1. In other words, the fault current in the machine is only 41 per cent of what it would have been had the fault been applied directly to the machine terminals. Then since the magnetic forces involved are proportional to I^2, it follows that $0.41 \times 0.41 = 0.17$; or the

internal short-circuit stresses due to magnetic forces are only 17 per cent of what they would have been for faults directly on the machine terminals at 100 per cent voltage. Considering the fact that the machine is designed to withstand faults at 110 per cent voltage, and must necessarily contain a considerable safety factor, it becomes apparent that the developed magnetic stresses within the machine occasioned by circuit-breaker fault tests is extremely moderate in comparison with the machine design specifications. Such stresses should not constitute a hazard to the equipment unless the machine is in a very defective condition from other causes.

Backup Protection

Backup protection for the test circuit breaker was provided by the 3-cycle line circuit breakers and the associated line relays supplying the fault current. For the majority of the tests the backup circuit breakers were the two station circuit breakers on Midway Line 1. Either one or the other circuit breaker was used for the moderate capacity tests involving only half of the station; and both were used to parallel the busses for the high-capacity tests. It is noted that the 3,500,000-kva rating of the backup circuit breakers is not exceeded for faults up to somewhat above 7,000,000-kva, as on the full-capacity tests the fault current is divided approximately equally between the two backup circuit breakers, one on each bus; and, in addition, the backup circuit breaker operating time allows for a considerable current decrement before contact parting, further reducing the duty on the backup circuit breakers.

Backup protection and relaying was provided in the following operational sequence as illustrated in Figure 6:

1. The test circuit breaker was relayed by means of an instantaneous overcurrent relay, using a minimum current setting to obtain the fastest possible relay time. This relay tripped the test circuit breaker directly. In the case of pretripped tests, this relay acted as backup against failure of the pretripping function. If, for any reason, both the pretrip and the overcurrent trip had failed to trip the test circuit breaker or the test circuit breaker had failed to clear the fault promptly, the following backup operation would have been initiated:

2. The directional ground relay on the line supplying the fault current would pick up to trip its associated line circuit breakers. This same operation would take place at the far end of the line, thus completely clearing the test circuit breaker from all power sources. If however, either or both of the backup circuit breakers had failed to trip, further backup protection would have been initiated as follows:

3. The TD relay (time-delay bus-differen-

tial trip) would have closed its contacts after approximately 7-cycles delay after receiving its tripping impulse and operate to clear all other circuit breakers from the station bus, thus removing all sources of power.

In order to prevent undesirable high-speed tripping of the backup circuit breakers when not required for protection, the first zone tripping contacts on the *Type GCX* distance line relays and the instantaneous contacts on the directional ground line relay were "papered-out." The second and third zones of the *Type GCX* relays and the inverse time contacts on the ground relay remained operable for the desired delayed backup protection. An oscillograph record was obtained of the trip current to the backup circuit breakers to provide a positive indication as to whether a test circuit breaker had cleared first in cases where the backup circuit breakers had operated during a test. The timing sequence shown in Figure 6 is only typical. Actual timing was varied slightly as particular test conditions dictated.

Current Measurements

Since all faults were single-line-to-ground, it was possible to measure fault currents by means of a 5,000/1 ampere (1-ampere secondary rating) through-type current transformer located in the connection to the grounded pole of the test circuit breaker. Maximum asymmetrical fault currents encountered during the tests did not exceed four times the nominal continuous rating, which was well within the acceptable range of accuracy. The secondary circuit of this transformer was used to operate one element of the 12-element laboratory oscillograph, for recording instantaneous values of fault current. High accuracy type bushing current transformers, located in the various steel tank type circuit breakers, were used in conjunction with the laboratory oscillograph to record instantaneous values of line-charging current during the line-switching tests. Current transformers of the 230-kv wound-type with a ratio of 300/1 ampere (1-ampere secondary rating) were used for measuring the line-charging current for the line-switching tests on the *Type FG-25* impulse circuit breaker.

Voltage Measurements

Instantaneous line and bus voltages were obtained and recorded on the magnetic oscillograph by two distinct and separate methods:

1. By means of a conventional capacitance potential device.
2. By means of a coupling capacitor connected as a capacitance potential divider, with the transformer removed, and used in conjunction with a specially designed electronic amplifier and magnetic oscillograph.

The latter proved to be the more accurate and superior method as it faithfully indicated d-c potentials trapped on line conductors as well as a-c transient voltages. The electronic amplifier was necessarily required when recording instantaneous voltages on the magnetic oscillograph because of the relatively large amount of power required to drive the vibrator. This very satisfactory and relatively inexpensive method of faithfully recording high frequency transient voltages was recently described in a paper[4] which presented the basic method and similar applications in detail.

Cathode-ray oscillograph (CRO) equipment was furnished and operated by both manufacturers to supplement and monitor other desired voltage measurements. For recording 230-kv line and bus potentials a coupling capacitor without transformer was connected directly to the deflection plates of the CRO tube, after having been previously modified by replacement of the bottom auxiliary capacitor unit by one with a capacity of about 2.5-microfarad. This modification re-

* C-φ of 100-mile line in parallel with 82-mile line. Equivalent to 182 mile line.

** "Normal" voltage across the circuit breaker is assumed as follows: At the instant of arc interruption, the crest value of voltage (138×1.414=196 kv) is left trapped upon the line, and 1/2 cycle later the bus has reached crest value, also 196-kv, but of opposite polarity. The vector difference of these two crest values, or 392-kv will therefore normally appear across the circuit breaker pole unit. The figures in the tabulation are multiples of this theoretical normal as obtained from the magnetic oscillograms

duced the available potential across the auxiliary capacitor to a safe value of approximately 60 volts. The potential appearing across the auxiliary capacitor was conducted to the CRO deflection plates by means of a 52-ohm coaxial cable. This arrangement constituted a true series capacitance potential divider circuit, linearily responsive to voltage and practically independent of frequency without phase angle error, within the range involved. The foregoing arrangement was used during various portions of the test series to record line-to-ground voltage; bus-to-ground voltage; and line-to-bus voltage; the latter indicating the voltage directly across a circuit breaker pole unit during line switching tests. This was considered of particular value as it was recognized that transient overvoltages within themselves can be objectionable, but the most objectionable situation which can occur, as far as the performance of the circuit breaker interruptors is concerned, is the condition wherein simultaneous over-voltages appear on both sides of the circuit breaker 180 degrees out of phase. The vector sum of such potentials could build up to very high values across the interruptor units, hence the particular interest in this type of measurement during the field tests.

Description and Results of Tests

Line Switching Tests Series "B"—*Type GO-2*

This series consisted of a group of 35 line-charging and line-dropping operations on a *Type GO-2* tank circuit breaker, after special 1,250-ohm wire-wound resistors had been installed across each interruptor for this specific test. This circuit breaker was installed and placed in operation in 1944. Table I summarizes the pertinent data obtained during this series of line-dropping tests. It is noted that there were no restrikes on any of the 30 3-phase tests (equivalent to 90 single-phase tests). The crest magnitude of the transient voltages during switching were very moderate and caused no concern. However, the excessively long interrupting time (resistor current) may cause difficulty, particularly on the unfaulted phases, in installations where high-speed reclosing operations are employed. The results also indicate that the circuit breaker was 93 per cent open on one test before the resistor current was inter-

rupted. The difference between 93 and 100 per cent, or the fully open position, appears to provide insufficient margin of safety.

LINE SWITCHING TESTS SERIES "O"—*Type GO-2*

After completion of the foregoing test Series "B," the special 1,250-ohm resistors were removed, the original 0.4 megohm resistors replaced and the circuit breaker restored to normal. This was followed by an identical test series, using the same bus voltage, line lengths and switching arrangement. Table I summarizes the test results of this series and Figure 12 shows a typical oscillogram. It is noted that 14 per cent of the tests had single restrikes and that one double restrike occurred on *Test 0-31*. However, these single and double restrikes are of a secondary importance as the magnitudes of the overvoltages resulting therefrom were not objectionable. This observation is also borne out by the absence of objectionable overvoltages from the cathode-ray records obtained on the far end of the transmission lines being dropped. A greater margin was provided for arc interruption than was provided by the low ohmic value resistors of Series "B," as evidenced by the fact that the maximum lift-rod travel was only 9 per cent of the total opening stroke at the point of current interruption. Based on a normal 18-inch stroke, this corresponds to approximately $1^4/_8$ inches of lift-rod travel. In general, it appears that the high ohmic value resistors (0.4 megohm per interruptor) are preferable to the low ohmic value resistors, even though they do not completely eliminate restrikes. No serious overvoltages were obtained by either the high or low ohmic value resistors, but the high ohmic value resistors permitted arc extinction within the specification time of 3 cycles.

An internal inspection of the circuit breaker after completion of each series of line-dropping tests revealed a minimum of contact pitting, carbonization, or oil discoloration. The appearance of the interruptors and the mechanical adjustments of the circuit breaker was completely satisfactory throughout.

FAULT TESTS SERIES "D"—*Type GM-3*

This series consisted of a group of nine single-phase-to-ground faults, using the standard AIEE duty-cycle of two close-open operations separated by a 15-second time interval. Two of the nine tests were with arcing faults. All fault tests were conducted on a special single-pole pneumatically-operated 230/196-kv tank *Type GM-3* oil circuit breaker, shipped to Grand Coulee specifically for this purpose. Table II lists the fault currents, interrupted kilovolt-ampere and other pertinent information. Figure 13 shows a typical oscillogram. The maximum total

[xo] O-18C-CO

† Test D-1-A is initial fault and Test D-1-B is fault after reclosure on same test. R indicates repeat of original test.

Notes: Arc did not re-ignite after circuit breaker reclosure on any arcing faults. Contact parting time 1.2-cycles for all tests except 1.1-cycles for Test D-6-A and B.

asymmetrical fault current interrupted in this test Series "D" was 18,200 amperes, corresponding to an equivalent 3-phase fault of 7,500,000 kva. No undue external indications of distress were apparent until the final full capacity *Test D-6-B*. On this test, the second half of the duty-cycle, a small puff of gas was noted to escape from the circuit breaker vent pipe, and the circuit breaker tank exhibited a visible jump which was accompanied by a light ground shock. After this test it was noted that the nuts on the four 1-inch anchor bolts could be turned down 1/8 to 1/4 inch, due to the loosening of these bolts in the foundation.

All interruptions were successful and were accomplished within the specification time of 3 cycles. A subsequent inspection of the contacts indicated that they were still in serviceable condition. Oil samples tested satisfactorily for dielectric strength.

Fault Test Series "F"—*Type GM-3*

After conclusion of fault test Series "D" the test circuit breaker was completely checked and overhauled and a complete set of new contacts installed. As reassembled for Series "F", the condition of the circuit breaker was equivalent to that of new equipment. Five additional 1-inch anchor bolts were installed around the circumference of the circuit breaker tank to assist the four original bolts which had been loosened during test Series "D." Test Series "F" was conducted in a similar manner to Series "D" except that "60-cycle" and faster reclosures were used to observe and determine the behavior, operating ability and possible signs of distress under reclosing conditions, for both solid and arcing faults. An adjustable electronic timer was provided for accurately timing the reclosing operation. This timer proved highly satisfactory. Test Series "F" was accomplished in two groups. The first group, consisting of *Tests 1–7* inclusive, was followed by a complete circuit breaker inspection and overhaul. A complete set of new contacts was installed, followed by the second group, consisting of *Tests 8–14* inclusive. The first group consisted of solid-ground faults and the second group consisted of arcing-ground faults. Inspection of the circuit breaker after each group of tests revealed all contacts and interruptors in a serviceable condition. All interruptions were successful and were well within the specification limit for interrupting time. Table II lists the fault current values, the equivalent of 3-phase megavolt-ampere and other pertinent data. The heaviest solid fault interrupted was 6,000 megavolt-ampere on *Test F-5-B*, and the heaviest arcing fault interrupted was 4,330 megavolt-ampere on *Test F-12*. The test circuit breaker was pretripped on the solid faults but not on the arcing faults, which accounts for the difference in interrupted megavolt-ampere between the two groups.

For the first group, *Tests 1–7* inclusive consisting of "O-CO" duty cycles on a solid ground fault, it was necessary to start with the test circuit breaker in the closed position and apply the fault with a station circuit breaker. All three poles were connected in parallel to distribute

the high fault current between the pole units, and the circuit breaker was placed between the test circuit breaker and ground. On the arcing-fault *Test 8–14*, inclusive, the reclosing time was successively reduced on each test to observe whether the arc would reignite after the initial interruption and high speed reclosure. Although the reclosing time was reduced to 12 cycles as indicated in Table II, the arc was sufficiently deionized in all cases to prevent reignition after reclosure. Wind velocity was considered to be zero during these deionization tests. *Tests 13–14* were run with a single unit on an isolated bus in order to include a wide range of fault current values, to substantiate the assumption that the arc would not reignite after faults of both high and low current magnitudes. All reclosures were successful.

Line Switching Tests Series "M"—*Type FG-25*

This series consisted of a group of 27 3-phase line switching operations on the *Type FG-25* impulse circuit breaker. This circuit breaker was installed and placed in operation in 1945. Table III summarizes the test results of this series and Figure 21 shows a typical oscillogram. Of the 27 3-phase tests, 7 were line-charging operations. On the balance of 20 3-phase line-dropping tests the average interrupting time was 2.32 cycles, of which 1.9 cycles represents the circuit breaker contact-parting time. In other words, the average arcing time was 0.42 cycle, or less than one-half cycle. The maximum interrupting time of any test of the series was 2.6 cycles and the minimum time was 2.1 cycles. There were no restrikes on any test and no indications of switching overvoltages on any of the records, regardless of the fact that the tests were conducted on a wide variety of line lengths and switching conditions. In conclusion, it may be stated that on the basis of test Series "M," the impulse

Figure 18. Typical oscillogram of single-phase fault test "H" *Type FG-25* impulse circuit breaker

circuit breaker exhibited an excellent capability for switching long, unloaded high-voltage lines, without restrikes, overvoltages or prolonged arcing. The extremely short duration of the arcing time prolongs contact life and reduces oil carbonization.

Fault Tests Series "H"—*Type FG-25*

This series consisted of 14 single-phase-to-ground faults. Table IV lists a summarized tabulation of fault currents and the equivalent 3-phase megavolt-amperes interrupted on each test. Figure 22 shows a typical oscillogram. This test series of 14 high-capacity fault-clearing operations might well have been considered a life test as well as an interrupting capacity test, due to the large number of interruptions without the benefit of internal inspections. The majority of these operations were at an interrupting duty of approximately double the nominal circuit breaker rating of 3,500,000 kva.

At the conclusion of the 14 high-capacity interrupting duty tests, the contact board was removed and the contacts inspected. All contacts were still in serviceable condition. Only one contact of the ten showed definite signs of distress, where one corner of the Elkonite contact tip had been undercut by the arc, but even this contact was still in a serviceable condition. There was little question but what the circuit breaker could have remained in normal line service and successfully carried load current without excessive overheating. Several fiber studs had failed. These failures were not considered serious in relation to the present series of tests, as the failures were such as to not interfere with the proper operation of the interrupter. The dielectric strength of the insulating oil was also satisfactory after the tests. All interruptions were entirely successful and were accomplished within the nominal 3-cycle interrupting-time rating of the circuit breaker. The average interrupting-time for all tests was 2.8 cycles, with a minimum of 2.6 cycles and a maximum of 3.0 cycles within the series. The circuit breaker demonstrated an excellent capability for repeatedly interrupting fault currents up to almost double its nominal rated capacity.

Line Switching Tests Series "P"—*Type FK-439*

This test series consisted of a complete group of 40 single-phase tests, and included 20 tests wherein the line was switched from a loaded bus, and 20 tests wherein the line was switched from an isolated bus supplied by two isolated generators. Four different line lengths were used to obtain the effects of several magnitudes of line-charging current, as follows:

1. A single conductor of Midway Line 1 with the other two conductors grounded, equivalent to about 100 miles of line;
2. Two conductors in parallel with the third conductor grounded, equivalent to about 200 miles of line;
3. Three conductors in parallel, equivalent to about 300 miles of line;
4. One conductor of Spokane Line 3 in parallel with three conductors of Midway Line 1, equivalent to about 382 miles of line.

The actual charging current in the latter case was 212 amperes at 233-kv, or 28,500 charging kva. The average interrupting time of all line-dropping interruptions was 5.45 cycles, with a maximum single test of

* Restrike obtained on this test

Average interrupting time of all tests from loaded bus, 233-kv ..... 5.4 cycles

Average interrupting time of all tests isolated from system, 241-kv ..... 5.4 cycles

Per cent of tests with restrikes from loaded bus ..... 33 per cent

Per cent of tests with restrikes isolated from system ..... 37 per cent

7.4 cycles and a minimum single test of 3.3 cycles. Table V summarizes the test results and Figure 17 shows a typical oscillogram. The pole-unit 1,200-ohm resistors were checked for continuity with an ohmmeter several times during the tests and at the conclusion of the complete test series, and were found to be satisfactory in every case. Single restrikes were obtained on 35 per cent of the tests but resulting overvoltages were only moderate. No multiple restrikes were obtained on any tests. No restrikes were obtained when dropping either 100 miles or 200 miles of conductor, corresponding to charging currents up to 122 amperes at 241 kv. However, when dropping 300 miles or 382 miles of conductor, corresponding to charging currents of between 152 amperes and 212 amperes, single restrikes were obtained on 63 per cent of the tests. The excessively long resistor current of 7.4 cycles would probably influence the feasibility of using this circuit breaker for high-speed reclosing duty, particularly if reclosing is attempted in less than 20 cycles.

Fault Tests Series "L"—*Type FK-439*

This test series, consisted of a total of 24 single-phase-to-ground faults on pole (1) of the *Type FK-439* oil circuit breaker. All faults were solid-ground on *A*-phase only, using "open," "close-open," and reclosing operations. Table VI lists a summarized tabulation of fault currents, equivalent 3-phase megavolt-amperes interrupted on each test, and other test data. Figure 18 shows a typical oscillogram. This test was performed in two major groups:

1. *Tests 1 to 9R*, inclusive using "open," "close-open" and standard 15-second duty-cycle operations,
2. *Tests 10 to 19*, inclusive, using high-speed reclosing operations and two additional standard duty-cycles.

After the conclusion of the first group, the oil was removed from the tank and a complete new set of contacts installed before resumption of the test series. In both cases the contacts appeared to be in serviceable condition, with the possible exception of one contact from the second group which had lost a small portion of its Elkonite tip. This contact would undoubtedly have still carried load current successfully but probably would not have withstood many additional full system fault tests. However, considering the excessively large number of high-capacity operations to which these contacts had been subjected, they were found to be in good condition. This *Type FK-439* circuit breaker successfully interrupted a large number of high capacity faults, up to and including 6,800-megavolt-amperes, with no apparent distress. The dielectric strength of the oil was satisfactory after the conclusion of the tests.

Conclusions

The successful performance of all the 230-kv oil circuit breakers at interrupting capacities approaching 200 per cent of

their nameplate rating was remarkable and gratifying. The confidence thus gained from these field tests in the design and performance of modern high-voltage circuit breakers will permit continued interconnection of our high-voltage power systems without fear of being limited by circuit breaker interrupting capacity or performance. After review and study of these tests the following conclusions were reached:

1. The many successful interruptions of 6,000,000-kva and more at 230-kv clearly indicate that 10,000,000-kva interrupting capacity 230-kv circuit breakers can be developed immediately and that even higher capacity circuit breakers are attainable.

2. From the reclosing performance of the circuit breakers it appears that no de-rating factor is required for one 20-cycle reclosure.

3. Successful performance of the circuit breakers at 12-cycle reclosing operations without reignition of the arcing faults indicates that faster reclosing speeds than 20 cycles are attainable.

4. The impulse-type stored-energy circuit breaker demonstrated superior performance during interruption of line-charging currents and fault currents.

5. The use of low ohmic value resistors in parallel with the interruptor units in tank-type circuit breakers permits flow of resistor current long enough to question performance on less than 20-cycle reclosures.

6. It has been conclusively demonstrated that field tests involving short-circuit values of 7,500,000-kva can be safely performed on an extensive interconnected power system without mishap, hazard to equipment or serious operating disturbances or delays in prearranged test schedules.

7. Such field tests are essential to permit the continued development of high-voltage transmission systems and equipment. High power laboratory tests would be inconclusive without field tests at actual system voltages to substantiate laboratory data. Valuable information is also gained on the performance of the transmission system under fault conditions. Without performance of these tests the immediate development of 10,000,000-kva interrupting capacity 230-kv circuit breakers would not have been possible.

Discussion

Philip Sporn and **H. P. St. Clair** (American Gas and Electric Service Corporation, New York, N. Y.): It is gratifying to see once again a high capacity high-voltage system made available for carrying out a circuit breaker testing program, and it is particularly gratifying to see the material advance in circuit breaker testing experience that has been accomplished by the tests described in the paper. Besides presenting the test results themselves, the authors have done well in our opinion to discuss the relative hazards of staged faults as compared with the normal hazard of lightning, and so forth, and to point out that these tests, as severe as they are, do not impose on generators and other equipment nearly as great a shock as their designs are intended to withstand. As a corollary, we believe they could well have added that if such tests had disclosed weaknesses, even resulting in failures, it would be better to find them out during carefully observed test procedures than during normal operation, particularly during critical peak load periods. We should like also to express the hope that the complete success of this program in its adherence to schedule and absence of unfavorable incidents, experiences which we have repeatedly checked on one system, will give courage and inducement to other systems to lend their facilities to the making of field tests which are so vitally important to the advancement of the circuit breaker art.

The results of these tests are of double value, including as they do, both no-load line switching tests, and high capacity short circuit tests. It is most significant and timely, we believe, that these tests have thoroughly explored the line-switching ability or characteristics of three types of circuit breakers, two of the conventional tank type using resistors to control overvoltages and restrikes, and one of a strictly stored-energy type, which, of course, requires no resistors.

As pointed out in a discussion we presented a year ago in connection with a paper by Leeds and Van Sickle,[1] the complete elimination of transient over-voltages due to switching on transmission systems may open up new possibilities for economies in the entire field of high voltage transmission. Substantially lower levels of insulation along the lines suggested in the recent paper by Sporn and Monteith[2] are believed to be feasible with respect to lightning and arrester co-ordination, but not without eliminating the more destructive effects of switching transients with their high energy content as compared with lightning transients.

While these tests seemed to demonstrate that the use of properly selected values of resistance across the contacts of conventional oil circuit breakers will limit the number of restrikes and prevent resulting overvoltages from reaching dangerous values, it was also shown that the resistors themselves may introduce undesirable effects, such as lengthening of the arc. It is clearly necessary to strike a balance or compromise between a resistance value low enough to control restriking effectively, but not low enough to cause excessive arc length which, of course, would interfere with successful ultra-rapid reclosing. Notwithstanding the confidence expressed by the designers that the right amount of resistance can be found to control both of these opposing effects within safe limits, if there is one convincing conclusion brought out by these tests, it is the clear-cut superior performance of the stored-energy type of circuit breaker in handling the line-charging tests with no restrikes whatever. Although it may be premature to draw final conclusions, nevertheless, in the light of these and other tests, the evidence seems to be accumulating that the stored-energy type of circuit breaker will probably be the better answer to the high-voltage switching problem, at least in the extra high voltage field where insulation economies may be greatest.

On fault-interrupting tests, all of the circuit breakers tested showed remarkably dependable performance, extending to duties well above design ratings. It is especially gratifying to note that these circuit breakers, regardless of type or manufacture, showed consistent ability to interrupt the highest faults repeatedly, including intervals below 20 cycles. This confirms again the conviction we have had for a long time and which we have repeatedly expressed before the AIEE that derating factors on circuit breakers in the high voltage classes, at least 115

kv and above, are not necessary and should be eliminated. In the light of these tests, on top of many others showing similar results, we again submit that the time has come for realistic recognition of these facts and the eliminating by the manufacturer of such derating factors.

2. TRANSMISSION OF ELECTRIC POWER AT EXTRA HIGH VOLTAGES, Philip Spora, A. C. Monteith. AIEE TRANSACTIONS, volume 66, 1947, pages 1571–82.

F. J. Fry (University of Illinois, Urbana, Ill.): This paper presents a group of tests on competitive apparatus with no attempt made to compare the performance of the apparatus other than in the one very significant way that all tests on both manufacturer's circuit breakers were successful. There are a few very general remarks from which it is possible to make very rough comparisons but, of course, the positions of the authors would obviously not warrant any detailed comparisons.

However, since this paper does present data which can be analyzed in some detail and since competitive tests are virtually unknown, it should be interesting from several viewpoints to indicate how the various manufacturers have dealt with the problems encountered in these high power and line charging current interruptions.

Considering the line switching tests series "M" *Type FG-25*. Here the contact parting time is 1.9 cycles, and on the basis of a consideration of pure sine waves of current in a 3-phase system if the circuit breaker was capable of interrupting when current zeros occurred immediately after contact parting the minimum possible interrupting time would be 2.23 cycles which corresponds very well to the tabulated data. On the basis of the same considerations the maximum possible interrupting time would be 2.40 cycles which is 0.2 cycle less than that listed. This discrepancy could be explained on the basis of nonsinusoidal wave forms for the current and slightly longer contact parting times for some of the circuit breaker poles. There is also the possibility of a probability of clearing at a current zero which occurs at very short contact spacing which would mean that sometimes current zeros which occur for very short spacings are passed by with a negligible build up of voltage while at other times these zeros correspond to circuit interruptions. In any case it is apparent that the impulse circuit breaker in this form gives the ultimate in charging current performance. The peak voltage withstand ability at a time of 2.4 cycles which corresponds to the quickest time of maximum voltage application is at least 70-kv per inch.

No data in these particular field tests are available on the *Type GM-3*, or other circuit breakers, using the multi-flow deion interrupters from which any detailed information can be gathered, however, for those who are interested in the possibility of making more accurate comparisons, the master of science thesis "The Design of Low Mechanical Energy Charging Current Interrupters" submitted by F. J. Fry to the University of Pittsburgh will be of aid.

Specific data from this thesis in which the multi-flow deion type interrupter is used with a very small oil driving piston show that for contact speeds and oil velocities comparable to those used on the impulse circuit breaker the multi-flow deion principle can perform equally satisfactorily in the sense of giving the ultimate in charging current performance. There is of course very much doubt that such performance is really necessary especially since the multi-flow deion interrupter with its delayed action piston has proved to be very satisfactory.

For the high power tests, series "L" on the *Type FK-439* circuit breaker, the quickest interruption was in 2.1 cycles corresponding to a moving contact position which is somewhere between the two exhaust ports for the arc subject to the cross blast of oil. In the total pole unit there is approximately 4.5 inches separation in the interrupting arcs at this time and six cross blasts effective.

For the fault tests series "F" on the *Type GM-3*, the quickest interruption was in 1.8 cycles which corresponds to a contact position in the interrupting gap somewhere in the exhaust region past the first orifice. The total separation per pole in the interrupting gaps is approximately 2 inches and there are 2 orifices through which oil is flowing. To consider an interruption at 2.2 cycles, there are four orifices per pole effective and a total interrupting gap separation of approximately 3.5 inches.

These tests indicate that the particular orifice type of interrupter tested can function successfully at gap separations which are smaller than for the cross blast type. This is especially significant when it is realized that there are but two multi-flow deion interrupting breaks per pole whereas there are six interrupting breaks in the *Type KF-439* circuit breaker.

By considerations such as these, one can secure data which show how the various manufacturers have solved interruption problems, and by intelligent customer analysis of competitive apparatus on tests such as presented in this paper, it is to be hoped that judgment can be made in a sound engineering way on the merits of particular circuit breakers.

M. H. Hobbs (Westinghouse Electric Corporation, East Pittsburgh, Pa.): This and the companion papers record another important landmark in the development and testing of high voltage circuit breakers. We, as manufacturers, are very appreciative of the attitude of the Bureau of Reclamation and Bonneville Power Administration in providing the facilities and co-operation without which the tests could not have been made. They were somewhat of a continuation of similar tests made in December 1945, when fault currents up to 4,370,000-kva were interrupted, which at that time was also the maximum available anywhere. We are gratified that both series of tests confirm so closely the prior tests in our own high power laboratory.

The results show the performance of three different designs of circuit breakers, of two manufacturers, all of which appear to have the ability to interrupt high kilovolt-amperes, as well as charging current, at 230-kv.

With reference to the fault current tests on the *Type GM-3* circuit breaker, the performance shown by oscillogram, Figure 13, is quite remarkable, the 7,500,000-kva fault being interrupted in a total time of 1.85 cycles after the energizing of the trip coil, with a contact parting time of 1.1 cycles, and the fault current actually remaining on the circuit less than one full cycle. Although this was the shortest interrupting time, it was also on the highest fault current of any of the tests, and the average for all such shots on this circuit breaker was 2.5 cycles, with a maximum of 3.0 cycles this time occurring on only two tests of relatively low kilovolt-ampere from a single generator.

Similarly, the switching of line charging currents by the *Type GO-2* circuit breaker was excellent, as reported in the table of tests and shown by the oscillograms. No serious overvoltages were obtained, and, when equipped with the standard high ohmic value resistors, for which the circuit breaker was designed, the interrupting time was uniformly less than three cycles, with restrikes eliminated on all except a very few interruptions.

We agree with the authors that the tests again point to the desirability of using high ohmic value resistors, as explained in the Leeds, Van Sickle paper a year ago.[1] The low ohmic value resistors, whether used on the *Type GO-2* or the *FK-439* circuit breaker showed poorer performance and longer over-all interrupting time, although overvoltages were moderate, as expected.

In arriving at the best type and design of circuit breaker, all factors and characteristics must be considered together. Thus, charging current interruption is important, but high speed here is not as essential as on heavy fault currents, where the shock to the system must be relieved as early as possible to maintain stability. Obviously, charging current interruption must be such as to prevent overvoltages occurring which might cause insulation breakdown.

An interrupter, such as the multi-flow type, in which the oil flow is controlled by the arc itself, provides higher generated oil pressure across the arc path as the current increases, and consequently will give optimum performance on the higher kilovolt-ampere faults, as demonstrated in these tests. At the same time, in line with the test reports, the interrupter gives uniformly good performance on charging current interruption, using the relatively small and simple auxiliary piston to force oil across the arc path. Such a piston takes little power to operate.

Over the years the metal tank circuit breaker has shown its ability to provide in the simplest and most rugged form a device which has kept pace with the demands of the industry for higher voltages, high speed of interruption of both fault and line charging currents, improved system stability, and fast reclosing. At the same time, the physical construction of the circuit breaker accommodates current transformers and bushing taps for potential without the addition of external high voltage apparatus.

In addition, due to more efficient interrupters, the tank diameter for 230-kv has been reduced until it is within a few inches of that of the older 138-kv circuit breakers, condenser bushing designs have been further improved, and maintenance has been lowered.

With reference to the authors' conclusions,

it does not appear necessarily that the derating factor for 20-cycle reclosing can be eliminated for all designs of circuit breakers. On certain circuit breakers and voltages this may be entirely possible, and the 10,000,000-kva circuit breakers purchased by the Bureau for Grand Coulee are given their full kilovolt-ampere rating on the basis of 20-cycle reclosing. The circuit breaker manufacturers' committee is at present reviewing the entire derating factor standard and is expected to have a new table available in the near future, which will give greater recognition to the improved interrupting ability of modern circuit breakers.

It seems evident from the Grand Coulee tests with reclosing on arcing faults that the minimum time of approximately 12 cycles for such reclosures is a limitation of the system and not of the circuit breakers now in production, and that the demands even of this large concentration of power may be adequately taken care of by designs which are available.

S. B. Crary (General Electric Company, Schenectady, N. Y.): The field tests reported in the paper will remain an important milestone in the development of high voltage circuit breakers for the following reasons.

1. The possibilities of higher interrupting capacity at the higher voltage levels demonstrated by these tests allow for simplified bussing arrangements and greater circuit load carrying ability. These are important factors in realizing improved transmission economy for systems in general as well as for the case of Grand Coulee as described in the paper.

2. Elimination of high switching surge voltages as a factor in system design makes possible continued rational reductions in line and terminal insulation levels resulting in further system economies.

High voltage systems may now be confidently designed using the high voltage system as the backbone taking full advantage of modern American circuit breaker characteristics of

1. Quick clearing.
2. Quick reclosing.
3. High interrupting capacity.
4. Elimination of excessive switching surges.

These four advantages collectively will allow for greatly improved high voltage systems of high loading, reliability, and economy. Transmission system designers, therefore, are placed at the threshold of a new era largely due to the contributions of forward looking switchgear manufacturers and system planners.

J. P. Stratford (Department of Water and Power, Los Angeles, Cal.): There is little in this paper on which to base a discussion as all tests were successful, conclusions are not debatable, and no theories are developed.

There are, however, several interesting features brought out such as the fact that the most desirable bussing arrangement at Grand Coulee is the ring bus with all transformer neutrals solidly grounded. This would produce a circuit breaker duty approaching 15,000,000 kva which is out of the question at this time. By installing transformer neutral reactors and special bronze conductors between the two switchyards it is possible to reduce circuit breaker duty to approximately 10,000,000-kva.

Tests were made on four circuit breakers (three tank type, and one impulse type) at interrupting capacities approaching 200 per cent of their nameplate ratings (3,500,000-kva) as well as line charging and line dropping tests.

All tests were satisfactory although the line dropping tests using 1,250-ohm resistors required excessively long interrupting time.

An interesting feature of the tests was the use of pretripping to increase the duty on the test circuit breaker as well as to reduce the time the fault remained on the system.

The Department of Water and Power, city of Los Angeles, in considering the advisability of increasing the interrupting capacity at the 138-kv oil circuit breakers on their system, found that an increase in interrupting duty on the 138-kv oil circuit breakers resulted in increases in interrupting duty on the lower voltage circuit breakers throughout the entire system. It would be interesting to know if a similar situation will not arise in the Pacific northwest when the duty on the Grand Coulee circuit breakers becomes 10,000,000 kva. Will this result in the necessity of providing higher interrupting duty circuit breakers on all the apparatus, connected with the Grand Coulee power plant?

Lloyd F. Hunt (Southern California Edison Company, Los Angeles, Cal.): The problems of conducting field tests are very numerous and complex. It is necessary to record test data and arrange the system so the planned short circuit will be properly isolated without materially interfering with the normal supply of power.

The authors and all departments who contributed to these tests should be highly commended for their careful preparation and execution of these tests.

There has been very much improvement in oil circuit breakers in the past decade. The methods of testing and interpreting results of tests are still confusing. It is difficult to establish the values in the tables from the oscillograms. It is apparent that, although these were field tests, laboratory technique was used to obtain these high values of interrupting duty. Pretripping to get a high d-c component and decrement is according to Standard C37. It is known that with high d-c component the fault current is easier to interrupt because the voltage and current are in phase. Therefore the circuit breaker will have a great deal more duty to interrupt the same kilovolt-ampere without a d-c component.

A better way to determine a safe value of interrupting capacity of the circuit breakers is to have tests that simulate the most difficult types of conditions to interrupt the arc. When the contacts of an oil circuit breaker are just starting to open thus a very short arc length, very small amount of energy is dissipated, the arc voltage being about 100 per inch under oil. Therefore a peak occurring at this point is not a fair one to use for determining the duty of the circuit breaker. From a long series of tests for a given interrupter a very good average of arc extinguishing contact separation has been established for various duties. It seems reasonable to measure the current at this separation point or a half cycle preceding. If this value of current was taken on the heavy tests at Grand Coulee it would bring the duty nearer the rating of circuit breakers. This should be thoroughly checked before any of these switches are subjected to 10,000,000-kva short-circuit without d-c components. The Southern California Edison Company has made many series of 230-kv oil circuit breaker field tests where circuit breakers have shown considerable stress with the same kilovolt-ampere duty using regular relay tripping that were approved on pretripped laboratory tests.

W. G. Hoover (Stanford University, Stanford, Cal.): The Bureau of Reclamation and co-operating organizations are to be commended on their interest in and willingness to make such important tests as described in this paper. The demonstration of the small shock to the station equipment and connected systems produced by pretripping the test circuit breaker should help make available more direct tests at other locations of large power concentration throughout the country.

The presentation of cathode-ray oscillograms of voltages produced across the test circuit breaker in both fault and line-dropping tests would have been of interest.

Both from the standpoint of the modern as well as the somewhat spectacular, this paper could well be called to the attention of students of electrical engineering as evidence that the "romance" of electric power engineering is far from a thing of the past.

O. A. Demuth (Bonneville Power Administration, Portland, Ore.): For several years, calculating board studies including proposed additions to the Bonneville Power Administration system, with very large concentration of generation at Grand Coulee and other projected dams, have clearly indicated that there was an urgent need for high-voltage oil circuit breakers having ratings greater than the 3,500,000-kva which manufacturers were offering, and that steps resulting in the development of circuit breakers having higher interrupting capacities should be taken. We believe that the Bureau of Reclamation engineers are to be commended for their foresight in this regard and for their willingness to use the Grand Coulee power plant generating equipment for such tests.

We also wish to compliment the authors of this paper on fully and adequately describing the conditions of the field tests, the results of which are presented in the two companion papers prepared by representatives of the manufacturers who participated in the tests. We are sure that these particular tests have resulted in materially contributing to the art.

The Bonneville Power Administration has frequently made staged tests on their system particularly at times when making major additions to the system. Such tests ordinarily include application of system faults and the interruption of line-charging current in order to check the operation of circuit breakers, co-ordinate protective equipment, and eliminate possible weak spots in equipment being added before it goes into regular operation. We are convinced that such tests have been well worth while, because

the analyses of oscillographic and other records obtained, and observations made during the tests, have not only given us as well as the equipment manufacturer valuable data for development of more reliable equipment and larger capacity high-voltage circuit breakers, but have also brought to light many weak spots—such as inadequate methods of relaying, improperly connected control and metering circuits, and improperly adjusted equipment and devices. If such conditions had not been found and corrected at that time, they might have later resulted in costly system interruptions, the cause of which then would have been difficult to isolate because such interruptions would have occurred at a time when no specially planned back-up protection, methods of observation, or metering were in effect.

The previous tests conducted by the Bonneville Power Administration were at points on the system remote from large generating stations such as the Coulee power house and, consequently, the faults to which the circuit breakers were subjected did not result in fault currents of the large magnitude obtained in the tests described by Killgore and Clagett.

We believe that field tests such as reported in the paper are mutually beneficial to the manufacturers of switching equipment and to the power utilities on whose system the equipment is to be used. System testing, when conducted under properly controlled conditions with suitable backup protection and adequate measuring facilities, in many cases is the only method by which the manufacturer and the utility engineer can be sure that newly developed equipment will be suitable for the operating conditions to which it will be subjected when used on large power systems.

T. M. Blakeslee (Department of Water and Power, Los Angeles, Cal.): With regard to line-switching tests on the *Type GO-2* circuit breaker, it is stated that the switch was 93 per cent open on one test before the charging current was interrupted. Although the dead-time characteristics of this resistor-equipped circuit breaker are not given, the difference between the maximum and minimum interrupting times presented in Table I indicates that arcing on the contacts interrupting the resistor current was in the order of five-cycles duration. Apparently the *Type GO-2* circuit breaker does not lend itself to the application of resistors which would guarantee a limit to overvoltages that may result from restriking when interrupting charging currents.

The tests with the resistor-equipped *Type FK-439* circuit breaker show that the resistor is in the circuit an appreciably shorter time than with the *Type GO-2* circuit breaker. The performance data given in the paper indicate a satisfactory resistor installation. Evidently there was no concern about the *Type FK-439* circuit breaker as no line-switching tests on this switch without the advantage of the resistor were made.

It would be helpful if the authors would give the dead-time characteristics of the two types of resistor-equipped oil circuit breakers in their closing discussion.

The results of the line-switching tests with the *Type FG-25* impulse circuit breaker confirm the experience of the Department of Water and Power. Tests with the impulse circuit breaker interrupting charging currents of 90 and 180 miles of 287.5-kv transmission line were made on the department's system in 1939 and 1943. Performance of this type of circuit breaker handling 80 amperes of charging current to 5 miles of 138-kv underground cable was demonstrated in 1944. In every case clean-cut interruption of the charging current occurred without restrikes and with no transient disturbance to system or circuit voltages.

The high-current interruptions reported by Killgore and Clagett were obtained by pretripping the test circuit breaker. This effected interruption at high rms values of current because of the heavy d-c component although the interruption was easier for the circuit breaker because of the reduced value of instantaneous voltage at current zero. While the interrupting claims of the paper are justified on the basis of present American Association Standard *C37.4-1945 Alternating-Current Power Circuit Breakers*, perhaps it is time that this standard be reviewed. Visitors from abroad are confused by this American practice which, they say, builds up circuit-breaker ratings unjustifiably. The growing international activities of the AIEE and the active interest in the International Conference on Large Electric High Tension Systems, might make it advantageous to review the American Standard in order to put it on a universal and more correct basis for rating the interrupting capacity of circuit breakers.

The authors and others associated with these tests are to be commended for the care and attention given to details of protection and measurement in this epoch-making work. They have made a valuable contribution which has led to an important step in the evolution of the circuit breaker.

C. L. Killgore and **W. H. Clagett:** The authors are very gratified at stimulating so much interest on the subject of high-capacity field testing of 230-kv circuit breakers, as evidenced by the large number of discussions which were received, and wish to thank S. B. Crary, W. G. Hoover, M. H. Hobbs, F. J. Fry, O. A. Demuth, Philip Sporn, J. P. Stratford, Lloyd F. Hunt, T. M. Blakeslee, and H. P. St. Clair for their constructive and pertinent discussions of the paper.

Both Hunt and Blakeslee point out the fact that even though circuit breaker testing with high values of d-c component of short-circuit current by pre-tripping is in accordance with present standards (*C37.4-1945, Alternating Current Power Circuit Breakers*), the interruption is actually easier on the equipment than if the same equivalent kilovolt-ampere were obtained without the d-c component, because the voltage and current are in phase. Since interruption of a short-circuit with a high d-c component occurs at reduced values of instantaneous voltage, it is easier from this standpoint for the circuit breaker to extinguish the arc. However, it was our observation during the circuit breaker tests that the mechanical shock to the circuit breaker was always noticeably greater on interruption of a short circuit with a high d-c component than on interruption of an equivalent symmetrical fault.

Pretripping during circuit breaker testing both in the laboratory and in the field is accepted practice. During laboratory testing, pretripping is generally used for the sole purpose of obtaining proportionately higher fault current by addition of d-c component at the instant of contact parting, thus resulting in higher interrupting duties than could be obtained otherwise. In the case of field tests, pretripping is likewise used for this purpose, but, of equal importance, it is also used to (a) provide a positive method of tripping the test circuit breaker by means of a simple "a" auxiliary switch, independent of relays and current transformers, with the latter equipment acting as backup protection, and (b) to provide high-speed removal of the fault from the power system to reduce system disturbances to a minimum. In view of the foregoing three functions, pretripping during the Coulee tests, particularly on the higher capacity shots, was adopted as the safest policy from an over-all system standpoint.

It is admitted that because of the high values of d-c component obtained on some of our near maximum tests, the computed kilovolt-ampere may be considered to be slightly inflated in respect to actual circuit breaker duty, or in respect to a similar test of equal kilovolt-ampere without d-c component, but during the Coulee tests this situation was more than compensated for by the fact that the tests were repeated a large number of times without the benefit of contact inspection. In fact, the test series as completed could have been considered more of a life test than an interrupting-capacity test, for in some instances as many as twenty faults were applied in one series; the purpose being to obtain data on contact deterioration and oil carbonization.

Hunt expresses apprehension over the use of new circuit breakers rated at 10,000,000 kva on the ultimate Coulee ring-bus without first testing them at this rating, without d-c component. As was pointed out in our paper, the concentration of eighteen 108,000-kw low-reactance generators at Grand Coulee power plant causes high values of d-c component for offset fault currents. The decrement factor for a fully offset fault at the 230-kv switchyard bus with all generators and transmission lines in service is approximately 1.35. On this basis the symmetrical component of a 10,000,000-kva short circuit for this particular application will not exceed 7,500,000-kva. Consequently, circuit breakers tested at 10,000,000-kva with some d-c component should be adequate for the proposed installation, particularly if they are given a number of repeated shots beyond the single standard duty-cycle required by the ASA standards.

Both Hunt and Blakeslee have suggested that the present ASA method of determining the interrupting capacity of circuit breakers should be reviewed. Blakeslee has suggested that curcuit breakers should be rated on a symmetrical current basis which is in accordance with European practice, and believes that the increasing exchange of technical knowledge through the International Conference on Large Electric High Tension Systems presents an excellent opportunity for discussion of this question. We agree with Blakeslee and have recommended to the EEI–AEIC–NEMA* Joint Com-

* Edison Electric Institute—Association of Edison Illuminating Companies—National Electrical Manufacturers Association.

mittee on Power Circuit Breakers that consideration should be given to rating circuit breakers on a symmetrical current basis. This procedure will greatly simplify the application of circuit breakers to power systems by eliminating consideration of the d-c component of fault current which depends for the most part on the subtransient reactance of the generators and the distance the circuit breakers are from the generators. Low reactance generators are not required for European power systems because of the relatively short transmission distances, which may account to a certain extent for the European method of rating circuit breakers. If a symmetrical current basis of rating is adopted it would be necessary for circuit breaker manufacturers to adequately design for any additional stresses imposed on the circuit breakers by the maximum possible d-c component of fault current. Hunt has suggested that the present method of rating circuit breakers at the instant of contact separation is questionable and believes that duty current should be measured at the average point of contact separation when the arc is extinguished, or 1/2 cycle earlier. This would in effect tend to rate circuit breakers on a symmetrical basis since much of the d-c component of current will decay in the additional contact parting time.

Blakeslee presents a comparison between the rather excessively long arcing time of five cycles for the *Type GO-2* circuit breaker, as compared with a considerably shorter time for the *FK-439* circuit breaker, when interrupting line-charging current. Both circuit breakers were equipped with low-ohmic value resistors during these tests. As pointed out in our paper, the *Type GO-2* circuit breaker was not designed for this type of resistor; the resistor having been applied to an early model for experimental purposes only. One of the basic factors contributing to the apparent difference in arcing time is due to the fact that the movable crosshead in the *Type GO-2* circuit breaker is engaged in finger contacts, whereas the *FK-439* circuit breaker utilizes butt contacts. This is not a valid comparison as the *GO-2* circuit breaker was designed for and is normally equipped with the so-called high-ohmic value resistors resulting in satisfactory performance. We concur with Blakeslee's comments regarding the experience which the Department of Water and Power, City of Los Angeles, has had, as well as similar comments by Sporn and St. Clair in regard to the clean interruption of line-charging currents by the stored-energy type of circuit breakers, without evidence of restrikes or transient voltages. While our papers stressed the fault tests at Coulee, the tests on interruption of line-charging current and the successful results obtained were of equal importance. As pointed out by Sporn and St. Clair, elimination of switching surge voltages permits lower insulation levels on high-voltage equipment.

Stratford has raised the question of whether the increase in circuit breaker duty at Grand Coulee to 10,000,000-kva will likewise result in a proportionate increase in circuit breaker duty throughout the Pacific northwest. The answer is yes. However, the increase in circuit breaker duty is due to the continued installation of new generating units at Grand Coulee, since only eight of the ultimate eighteen units are installed at present. Calculating board studies of a large number of schemes for bussing the eighteen generating units, of 108,000-kva each, has indicated that it makes very little difference to the rest of the system, in respect to circuit breaker duty, how Grand Coulee is bussed. However, increased short-circuit current only reaches out to the first stations on the 230-kv transmission system, approximately 100 miles in each of three directions. The effect upon circuit breaker duty beyond the first station is negligible.

We appreciate the comments of Demuth, Sporn, St. Clair, Hunt and Hoover that it was gratifying to see a high-capacity interconnected power system used for field testing, and it is our hope that the successful performance and lack of disturbances on the system during these tests will encourage others to use their power systems for field tests. Such tests are of mutual benefit to both the manufacturers and power system designers and operators, and we believe they are essential to the continued development of the electrical industry. We would like to repeat Sporn's and St. Clair's comment that the hazards of staged fault tests such as those at Coulee are much less than the normal hazards of lightning, and the shock to the generators and other equipment is also much less than that for which they were designed. We agree that it would have been well to point out that if the tests disclosed equipment weaknesses, it would be better to find this out during carefully observed field tests than during normal operation.

Hobbs points out that while the Coulee tests indicate no de-rating factor is required for one 20-cycle reclosure on the circuit breakers tested at Coulee, this does not necessarily mean it can be eliminated for all circuit breakers. Our comments in respect to this matter apply to high-voltage circuit breakers of the 115-kv class and above, and we are convinced on the basis of the tests at Grand Coulee that no de-rating factor should be applied to high-voltage circuit breakers. We agree with Hobbs' observation that the speed with which an arcing fault can be reclosed without restriking is a function of the power system and not a limitation of the circuit breaker. Our tests indicate that modern reclosing circuit breaker designs will permit reclosing in 12 cycles or less.

Crary's comment that the field tests at Grand Coulee power plant are an important milestone in the development of high-voltage circuit breakers is appreciated. We consider the development of ultra-high interrupting capacity circuit breakers as one of utmost significance to power system designers and planning engineers since higher interrupting capacity circuit breakers permit simplified high-voltage bussing arrangements and greater load carrying capacities. The development of 3-cycle clearing, 20-cycle reclosing and 10,000,000-kva interrupting capacity circuit breakers which eliminate overvoltages from switching surges was only made possible by continued engineering development and foresight by the manufacturers and confirmation of new circuit breaker designs by field testing.

The authors wish again to acknowledge the excellent co-operation and assistance of all those who participated in these tests and especially that of L. N. McClellan, assistant chief engineer of the United States Bureau of Reclamation, whose vision and courage made these tests possible.

A Faster Telemeter for Carrier-Current Channels

Synopsis: This new frequency-type telemetering system combines continuous measurement and fast response with high accuracy and stability of calibration. It uses as a translating means an alternating electric signal whose frequency is directly proportional to the measured quantity. This signal originating in a contactless transmitter can be used to modulate or key carrier-current channels of conventional fixed frequency types. It is the frequency of this signal rather than its magnitude which is detected by the receiver and converted without moving parts into a proportional direct current sufficient to operate a conventional indicating or recording instrument. This system in its basic form was developed to telemeter a-c watts, vars, volts, and amperes. Auxiliary equipment is available to permit telemetering practically any other electrical or nonelectrical quantity.

ELECTRICAL telemetering involves conversion of the quantity being telemetered into some proportional electrical quantity for the purpose of transmission to the distant receiving instrument. This implies a separation of the primary detector and the end device.[1] For many purposes, especially when used in automatic control schemes,[2] such as tie-line load control, it is essential that this conversion into the proportional intermediate quantity for transmission, and the subsequent conversion of that quantity into the final reading or control signal, be accomplished with minimum time lag. For a particular control purpose where it is desirable to introduce a time lag to make the automatic controller unresponsive to minor fluctuations in the controlled quantity, the lag is preferably provided, in adjustable amounts, in the controller itself.

For many telemeter applications involving automatic control a telemetering system, involving discontinuous action, cannot be tolerated, as it would seriously handicap the smooth, continuous, and timely action of the controller. An ideal telemetering system must, for best flexibility, not only have a rapid response, but it also must provide a continuous output signal.

Where a carrier-current channel is used, it is essential that the telemetering system require as narrow a carrier-frequency band width as possible. A high degree of accuracy, stability of calibration, ease of calibration and maintenance, and long life are additional characteristics to be sought in the ideal telemetering system.

The torque balance telemeter[3] meets all of these requirements, but is only applicable to well-shielded full metallic pilot wire channels.

Wherever distances are at all appreciable, carrier-current channels are usually necessary or at least preferred for telemetering.[4] Where power transmission lines are available, such carrier-current channels will usually employ frequencies somewhere in the 30 to 200 kc band, the particular frequencies being carefully chosen with a view to avoiding interference with other carrier facilities on the same or neighboring power systems.

Hitherto most telemeters for use with carrier-current channels have employed at the receiver an essentially square wave impulse signal, the rate of which, or the duration of which, could be varied in proportion to the magnitude of the quantity to be telemetered. With such impulse transmission, the telemeter receiver action has been very slow in following a rapid change in the measured quantity, actually discontinuous, or both. Because transmission of impulses by a carrier-current channel involves square wave keying, (essentially modulation[5] by a rectangular wave of signal frequency), simply increasing the frequency of impulses transmitted is not ordinarily an acceptable method of increasing the speed of response. This is because the required carrier band width, which is relatively large due to the square wave keying, is further increased by the faster keying rate, with the consequent reduction in the number of simultaneous readings that can be transmitted by the same carrier-current channel.

The New Fast Responding Frequency-Type Telemeter

To overcome these inherent difficulties in impulse telemeters and to eliminate sources of mechanical maintenance problems, yet without requiring unusual or undesirable types of carrier-current channels, the new frequency-type telemeter as shown in Figure 1 was developed. In this system the frequency of the transmitter signal varies in proportion to the magnitude of the measured quantity, over the range from 6 to 27 cycles per second. Frequency was chosen as the quantity to be recognized by this system because it is entirely independent of the transmission channel characteristics which are variable in nature. This range in frequency was selected to provide the most desirable balance between fast time of response, minimum carrier band width requirements, and minimum instrument damping. Higher frequencies would require excessive band widths; lower frequencies would require excessive damping, destroying quick response. The use of a sinusoidal transmitter signal, instead of the more common square wave impulse signal, permits better utilization of the carrier-current equipment of the type employing audio tone modulation of the

Figure 1. Frequency-type telemetering system

carrier. The frequency-type telemeter is a logical outgrowth of the magnetic impulse telemeter,[6] an improved form of which, as long ago as 1936, was provided with a photoelectric impulse-originating device and a voltage squared constant torque driving element in the transmitter. The 1936 receiver, however, was a thermal storage microammeter and was consequently somewhat sluggish, besides not being suitable for recording or control initiating purposes.

The Transmitter

Figure 2 illustrates functionally a telewattmeter transmitter.

The primary detector is a watthour meter of standard construction. It is connected to the circuit to be measured in the usual manner, and produces a shaft rotation at a speed which is proportional to the input watts. Similar detectors can be used to measure vars, a-c volts, or a-c amperes.

A voltage whose frequency varies in proportion to the measured quantity is generated by means of a photoelectric pick-up actuated by the rotation of the watt-hour meter shaft. A disk having a serrated edge is fastened to the watthour meter shaft. Located above the serrated disk is a light source, and below it a photoelectric tube, arranged so that rotation of the disk modulates the light beam directed on the tube. The shape of the serrations is such that a sinusoidal output voltage is obtained from the photo tube. The number of serrations is such that the frequency of the output voltage, with maximum rated input, is approximately 27 cycles per second.

The output of the photo tube is fed directly to a cathode follower, which serves primarily to reduce the output impedance of the pick-up mechanism. The cathode follower is physically located close to the photo tube, and, by its use, interference from external electrostatic and electromagnetic fields is made negligible.

The output voltage from the cathode follower is fed to a two stage push-pull amplifier of conventional design. The amplifier output is transformer coupled, thus providing complete electrical isolation. The amplifier also may include and operate an electromechanical relay when required for keying. The voltage and power output of this amplifier are of sufficient magnitude to operate most carrier-current equipments directly.

Figure 2. Frequency-type telemeter transmitter

Schematic functional diagram

An additional torque-producing mechanism is arranged to act on the watt-hour meter shaft, for the purpose of providing a finite shaft rotation when the measured quantity has zero magnitude. By this means, a definite distinction is made between zero input and inoperative transmitter, thus providing at the receiving station an indication of transmission outage. This means also is used to provide zero center operation. This additional torque is produced by a voltage squared type watt-hour meter element which utilizes the serrated disk as its driven member. A resistor is connected in

Figure 3. Frequency-type telemeter receiver

Schematic functional diagram

series with one of the element windings to provide the necessary calibration. This resistor has essentially a zero temperature coefficient, and is made very large compared to the resistance of the element winding in order to minimize ambient temperature errors. The voltage-squared element is excited from the station supply through a voltage regulating transformer, which provides a constant output voltage over normal variations in input voltage and frequency. Thus the torque produced by this element is constant, and adds directly to the torque produced by the primary detector. The constant-torque element is normally adjusted to give an output voltage whose frequency is six cycles per second with zero input to the primary detector (for zero-left operation). Thus the normal operating frequency range of the transmitter is from 6 to 27 cycles per second.

The transmitter is comprised of four physical components, the watt-hour meter mechanism, the amplifier, the voltage regulating transformer, and the constant torque adjusting resistor as shown in Figure 1. The watt-hour meter mechanism includes the primary detector, the photoelectric pick up, the cathode follower, and the constant torque element. This component very closely resembles a conventional 3-element switchboard type watt-hour meter in appearance, construction and mounting. The amplifier unit, including the electronic power supply, is arranged for standard rack mounting in either vertical or horizontal position. The voltage regulating transformer and the constant torque adjusting resistor have their own mounting means; each is arranged for behind-the-panel mounting.

Calibration of the transmitter primary detector is accomplished by the usual watt-hour meter practice, and requires no new technique or equipment. The initial factory calibration of the constant torque element is made by adjustment of the load resistor. Subsequent recalibration, should it be necessary, can be made with the normal watt-hour meter type of torque balance adjustment included in the voltage squared element, which provides ample range for normal recalibration. This calibration may be made using the same stop-watch technique employed to calibrate watt-hour meters.

The Receiver

The receiver is a frequency meter with a linear scale and with a high degree of immunity to response from interfering signals. Its purpose is to receive a frequency signal of from 6 to 27 cycles per second and to furnish a continuous, fast responding output to operate standard indicating, recording or control initiating devices. Since totalizing with the output of other receivers is often required, its response must be linear with respect to the input frequency. Most important of all, its response must be consistent, it must have long life stability, comparable to that of the transmitter.

The receiver is shown in simplified functional form in Figure 3. Auxiliary means are required to prepare the signal for the receiver's primary detector. These consist of a coupling transformer, a filter network, a limiting amplifier and a power amplifier. The primary detector itself is a saturating transformer and rectifier, the secondary output of which has an average value dependent only on the frequency of the input signal. Intermediate means are required to supply power to the electronic components, to furnish a regulated voltage, to provide a biasing current, to provide ambient temperature compensation, and to provide full and light load adjustments. The receiver output signal is suitable for operating various end devices,

such as a D'Arsonval indicator, a recorder, a control initiator, or means for totalizing.

Auxiliary Means

The various auxiliary means shown in Figure 3 constitute an extremely important portion of the receiver. In preparing the input signal for the primary detector, the coupling transformer insulates the receiver circuits from the carrier channel.

The filter eliminates the audio tone frequencies and assists the limiter in accomplishing the important function of eliminating unwanted signals. The amplifier is provided to insure complete saturation of the transformer.

One of the most severe situations where the elimination of unwanted signals is necessary arises when the receiver is one of several used with carrier-current equipment designed to transmit a number of signals over a single carrier-current channel. This is usually done by modulating audio tones in the range from 460 to 3,070 cycles per second with the output signal of the telemeter transmitter, mixing the audio tones and modulating the carrier frequency with the combined signal. At the receiver, the carrier is demodulated; the audio tones separated by filters, and each audio tone demodulated to obtain the telemetered signal.

In this case, two major types of interference are present. Both are due to the fact that the separation of the audio tones in the carrier-current equipment is not perfect. The first interference possibility is encountered when the desired signal is zero. The interfering signal is then the only input to the telemeter receiver, but its voltage magnitude is normally low. To provide for this situation the receiver amplifier is biased so that any signal below six volts is indicated as no signal.

Another interference situation occurs when both a desired and an undesired signal are present in the telemeter receiver input. A simple method of eliminating the effect of this interference signal is to have the telemeter receiver count the number of times the signal crosses the zero axis. This makes it practically independent of wave shape. It is accomplished in the limiting amplifier shown schematically in Figure 3 by delivering an essentially rectangular wave to the amplifier independent of the wave shape of the input signal.

However, the bias is selected so that any original signal less than six volts will deliver a signal to the second tube entirely below cut-off and will result in no plate signal to the amplifier. This novel method of eliminating both types of interference signals in a frequency meter has proved satisfactory and makes the receiver extremely flexible as far as use with various types of carrier-current equipment is concerned.

Primary Detector

The rectangular wave output of the amplifier is impressed on the saturating transformer, shown in Figure 3, and the core is saturated by flux in opposite directions each half cycle. The secondary current per half cycle is therefore

$$2F\int_{-\phi_m}^{+\phi_m}\frac{N}{R}d\phi=\frac{4Nf\phi m}{R}$$

where

N = number of turns on saturating transformer secondary
ϕ = transformer flux and ϕ_m = maximum flux
f = frequency
R = resistance of secondary circuit

Special precautions are taken in the choice of material and the shape of the core iron to insure that ϕ_m is a constant for any exciting voltages of the range to be encountered. The current per half cycle is therfore proportional to the frequency only, since the resistance R can be kept constant. This proportionality exists up to the maximum frequencies encountered in use. The stability of the primary detector is thus dependent only on certain very stable magnetic proporties of the core iron.

If during test, excessive frequencies are impressed on the transformer, the time constant is such that at the higher frequencies the flux cannot build up to values that will result in serious overcurrent

Intermediate Means

The output from the saturating transformer, which is a wave of positive and negative pulses, is rectified as shown schematically in Figure 3. The average d-c component is suitable to operate a D'Arsonval instrument to obtain an indi-

cation or a record. The transmitter has a constant biasing torque corresponding to six cycles (for a left instrument) which results in a receiver output when the transmitter output is zero. To take care of instances where the zero-input signal is not desired, there is generated in the receiver a constant negative current, furnished from a standard type power supply and voltage regulator. A resistance to adjust this constant current acts as a zero adjustment for the receiver. With this arrangement it is possible to distinguish three types of zero reading. The sub-zero from the constant current indicates receiver operation but no input signal, not even the six cycles. A steady zero indicates the receiver is not operating. A zero reading with a slight six cycle vibration indicates that the system is functioning with six cycles (zero magnitude of quantity telemetered for left zero scale ranges) being indicated. These features are an aid in checking the equipment after installation, or in case of outage of the carrier channel. In addition, sub-zero readings can be used for special signaling purposes.

Conservative design in the use of electronic tubes insures relatively long life; and outputs large enough to allow proper swamping resistors, as shown in Figure 3 to obtain good temperature compensation and to swamp out the effects of rectifier changes are characteristic of the high accuracy and good stability of the receiver.

Adjustments at both the zero point and an up-scale point are available and are indicated in Figure 3. Changing the zero point will alter all points on the scale by the same amount. Changing the up scale point will alter the zero by about one quarter the amount of the up-scale point change. Both adjustments are simply made and can be done independently of the transmitter.

End Device

An indicating end device is shown in Figure 3; however an indicator, recorder, or both can be used if the proper equivalent load is maintained. These end devices have a full scale rating of one milliampere. Where extreme accuracy is required, accurate end devices may be used. Where less accuracy is needed, lower cost instruments are suitable and useable in the system.

Performance Characteristics

A typical telemetering system might consist of a telewattmeter transmitter, a carrier-current channel and a telemeter receiver arranged for operating an indicating or recording instrument. Typical performance data for such a system are given in Table 1. The effects of the end device are not included, since this component may be selected from the wide variety of available instruments. Although the accuracies shown are typical, adjustments are furnished which permit the attainment of greater accuracies if under certain conditions it is desirable.

Carrier Channel Requirements

The 6 to 27 cycle frequency range utilized by the frequency-type telemeter is entirely suitable for either amplitude-modulation of a fixed audio-frequency tone that modulates the carrier frequency proper, or keying, electronically, a frequency-shift carrier telemeter channel. It is somewhat low for convenient direct amplitude-modulation of carrier frequencies in the 50 to 200 kc band. When keying a frequency shift channel it is convenient to have one carrier-current frequency transmitted during positive half cycles of the 6 to 27 cycle telemeter frequency, this carrier-current frequency being replaced by a slightly different frequency during the negative half cycles. Since the frequency shift is small, a large number of quantities can be telemetered simultaneously over the same route. Another method of telemetering a number of quantities over the same wires is to modulate audio-frequency tones that modulate the carrier. By the use of several simultaneous tones, a number of telemeter readings can be transmitted by the same carrier frequency. Of course, wherever more readings are involved a number of carrier frequencies can be used in the 50 to 200 kc frequency band.

The output of the amplifier associated with the telemeter transmitter is approximately 30 volts, at all frequencies, when feeding into an impedance of 50,000 ohms. The telemeter receiver requires an input of approximately 15 to 30 volts, across an impedance of 10,000 ohms, from the associated carrier-current receiver. Both the output characteristics of the transmitter and the input characteristics of the receiver are therefore suitable for use with commercial carrier-current equipment.

Table 1. Typical Performance Data

	Per Cent of Full Scale
Accuracy	1.0
Precision (repeatability)	0.5
Influences:	
Voltage (±10% of rated)	1.0
Temperature (±25 C from 25 C)	1.0
Frequency (±0.5% from rated)	1.0
Speed of response	Instantaneous (Less than 1 second)

Figure 5. Frequency-type telemeter receives applications

Transmitter Applications

Figures 4 and 5 cover various ways of utilizing the frequency-type telemeter and show a number of combinations with other telemetering equipment. For carrier telemetering of quantities other than watts, vars, a-c amperes or volts, and for totalizing, auxiliary devices are used.

For the very common requirement of totalizing watts or vars at the transmitting end of the channel, torque balance telewattmeter transmitters may be used to advantage, Figure 4a. The paralleled d-c milliampere outputs of these transmitters are converted, with negligible time

lag, into proportional single phase watts by a torque balance converter.[7] The converter single phase output is suitable for directly operating a frequency-type telemeter transmitter. This method of totalizing is used when lack of a common source of potential or other considerations preclude paralleling current transformer secondary windings through auxiliary current transformers to operate a single telewattmeter transmitter.

The torque balance converter is also applicable for telemetering d-c milliamperes. The milliamperes might be obtained from a torque-balance telemeter channel from a nearby location, such as for forebay water level telemetering. Such an application is illustrated in Figure 4*c*.

For telemetering of mechanical position, such as transformer tap position, the position is converted into a proportional alternating voltage for telemetering, Figure 4*d*. This can conveniently be done by a small rheostat or tapped resistor across which regulated a-c voltage is maintained.

When a torque-balance converter is used with a frequency-type telewattmeter transmitter for telemetering d-c volts, such as the field volts of a synchronous generator or condenser, or d-c millivolts from a shunt in a d-c circuit, the torque balance converter is built with a d-c voltmeter, Figure 4*e*, or millivoltmeter Figure 4*f* basic element, instead of the usual d-c milliammeter element. When the source of direct voltage to be measured must not be called upon to supply any current, for example, in the case of thermal converters, thermocouples, or retransmitting slide wires in telemeter recorders, an electronic high speed self-balancing potentiometer is used between the direct voltage to be measured and the torque-balance converter. This potentiometer provides a d-c milliampere output proportional to the millivolts, or even microvolts, input to it, Figure 4*b*.

Receiver Applications

When it is necessary to totalize several frequency-type telemeter readings, and simultaneously provide individual readings and subtotals, or when it is necessary to employ individual telemeter receiver output for automatic control purposes, it is advisable to use the torque-balance telemeter retransmitter. By this means the desired milliampere range is obtained with negligible additional time lag, Figure 5*a*. The use of such a retransmitter also makes it possible and convenient to totalize torque balance telemeter readings together with frequency-type telemeter readings. When totalizing with other types of telemeters providing only d-c millivoltages from their receivers, a self-balancing potentiometer will convert such millivoltages to proportional d-c milliamperes that can be totalized with the d-c output of the frequency-type telemeter receivers.

If integration of frequency-type telemeter readings, either individual or totalized, is desired at the receiving point to provide kilowatthour or kilowatt demand readings, this is readily accomplished by means of a torque-balance converter, the single phase a-c output of which can operate one or two watt-hourmeters, one for each direction of flow, in the case of reversible flow. The watthour meters can have kilowatthour registers and also, if desired, contact devices to operate any conventional type of block interval demand meters, for one or both directions of energy flow, Figure 5*b*.

For telemetering a system total or subtotal load, as totalized at the dispatcher's office, to individual generating stations for their guidance the system shown in Figure 5*c* is applicable. In this case, outage of one or even all telemeter channels need not mean dispensing with the totalized reading, as a manually-set torque-balance load injector[7] can be used to replace the missing telemeter reading or readings with approximate exactness.

When large diameter indicating receivers are desired, these may be selsyn operated from transmitting selsyns mounted in the strip chart recording milliammeters, via indication transmitters as torque amplifiers.[8]

A system incorporating most of the foregoing applications has been in service for some time to obtain operating data. The equipment is illustrated in Figure 6.

Conclusions

The new fast responding frequency-type telemeter represents a definite forward step in the art of telemetering by carrier current channels. Although time-

tested basic principles are used, new frequency measuring techniques, new materials, and refinements in well-known principles have resulted in:

1. Instantaneous response, without overshoot.

2. A high degree of accuracy, stability of calibration, and precision.

3. Continuous receiver output signal.

4. Suitability for use with modern power line carrier-current telemetering channels of the usual types.

5. Flexibility of application to a wide variety of telemetering problems.

6. Ease of adjustment and calibration.

7. Absence of contacts and electromechanical relays.

8. Minimum of moving parts.

9. Eminent suitability as a component of automatic control schemes where both high speed and continuous response are required.

Discussion

E. W. Kenefake (General Electric Company, Syracuse, N. Y.): The author's paper and presentation gives an excellent description of a new telemetering system for carrier-current channels. I would like to add a few additional comments concerning its applicability to carrier-current channels because I believe it is the first major development aimed strongly in this direction.

The important contribution which the authors have made is the use of a telemetering quantity to be transmitted which fits carrier-current channels. This quantity must not require too much band width and be able to cope with variations in the carrier-current channel such as may be caused by carrier attenuation, voltage supply variation, and so forth. Modulation of the magnitude of some quantity such as phase angle, voltage, or pulse width does not fill these requirements nearly as well as a variable frequency.

In regard to band width, practically all carrier channels can accommodate a band width of around 50 cycles without undue hardship. In practice, it would not be advantageous from a carrier-current standpoint to go much lower in frequency but a higher frequency would begin to waste band width. Because the quantity to be transmitted modulates the carrier or a subcarrier, the band width required is twice the highest frequency component that has to be transmitted. Therefore, some low frequency range, such as 6–27 cycles, is preferred.

For example, on narrow band crystal controlled frequency shift equipment with an 0.08 per cent shift in frequency, the band width is 80 cycles at 100 kc; therefore, the limit on the number of channels that can be grouped together is still limited by the carrier current equipment and not by the telemetering scheme. The choice of quantity to transmit, therefore, stems from what is convenient and economical to do with carrier equipment as well as from the characteristics of existing carrier equipment. The same frequency differential could be used at a higher frequency, such as 249–270 cycles, but then the carrier channel would have to provide a band width of 540 cycles as opposed to 54 cycles. Under these assumed conditions, only 1/10 the number of telemetered readings could be transmitted over a given carrier channel.

Another point to emphasize is the use of input and output transformers on the telemetering receiver and transmitter suitable for the 6–27 cycles which enables the system to be coupled properly to various carrier-current equipments quite readily.

Basically, this telemetering system employs frequency modulation because of the variable frequency of 6–27 cycles and the limiting in the receiver, and is the main reason it enjoys such freedom from interference and variation in the transmission channel. From a carrier-current viewpoint, no telemetering system is useful for carrier-current channels unless it can tolerate variations in the transmitting medium.

G. S. Lunge (General Electric Companys Schenectady, N. Y.): Kenefake has pointee out that while this new telemet er dod require a 54-cycle band width, this is within even the extremely narrow band width used by a crystal controlled frequency-shift carrier-current channel, at least for carrier frequencies from 90 to 200 kc. For carrier frequencies in the 30 to 90 kc range, it is necessary to forego the use of crystal control when a frequency shift carrier-current channel is used with this new telemeter. This will seldom prove to be a hardship, because of the reduced line attenuation at these lower frequencies and because it is still possible to handle three such carrier telemeter channels with the same line tuning and coupling equipment as would be needed, for example, for a single-frequency carrier telephone channel.

Most carrier-current telemetering channels of either the frequency-shift or the audio tone-modulated type now in service were designed for impulse transmission, initiated by a single contact in the telemeter transmitter. Obviously, some modifications in such carrier-current or audio tone transmitters and receivers are necessary to adapt them for use with the new telemeter transmitter and receiver described in this paper, which contain no electromechanical relays or contacts.

Performance Test of the Allgemeine Elektricitats Gesellschaft Free-Jet Air-Blast 220-Kv 2,500-Megavolt-Ampere Reclosing Circuit Breaker

ALEXANDER DOVJIKOV
MEMBER AIEE

CLIFFORD C. DIEMOND
MEMBER AIEE

Synopsis: Tests of a representative sample of this circuit breaker were made on the system of the Bonneville Power Administration in order to provide an opportunity for American manufacturers and operating engineers to study the operation of this circuit breaker in interrupting faults and line charging currents. A single pair of interrupting contacts in open air, ease of contacts visual inspection, maintenance and replacement attracted much attention and favorable comment, particularly from operating engineers. The circuit breaker successfully interrupted fault currents in about six cycles (average) as compared with three cycles of fast oil circuit breakers of American manufacture. Interruption of line charging current, although successful, was accompanied by many restrikes. It is hoped that these tests and the analysis of the test data will facilitate development of an American circuit breaker which will retain the favored features of the European prototype but will be faster in interrupting fault currents and practically free from restrikes in interrupting line charging currents.

AT A MEETING of the Technical Industrial Intelligence Division of the Department of Commerce in Washington on July 19, 1945, recent types of German circuit breakers were described by technical consultants who had just returned from Germany. It was recommended to the committee and to representatives of electrical manufacturers and utilities who were present that certain of these 115- and 230-kv circuit breakers be tested in this country.

The system of the Bonneville Power Administration, in connection with its rapidly growing generating capacity and transmission lines, requires a large number of fast reliable circuit breakers of very high interrupting capacity, and therefore, Bonneville Power Administration engineers are interested in circuit breaker developments which permit the elimination of the large amount of oil used in conventional circuit breakers and the necessary oil storage and oil handling equipment. Decreased fire hazard, greater ease of maintenance, rapid reclosing ability, and the possibility of single-pole operation are other factors which resulted in the agreement of the Bonneville Power Administration to test the German circuit breakers.

The purpose of the tests was not only to establish the operational characteristics of this particular circuit breaker, but to provide an opportunity for representatives of the American electrical industry to observe this type of circuit breaker in action and, by analysis of records obtained during the tests, to design an American air-blast circuit breaker which may retain the comparative simplicity of the German prototype and at the same time would be faster (at the most, three cycles), built for higher fault-interrupting capacity, and better adapted for interrupting large charging currents of long, high-voltage transmission lines.

The circuit breaker was first shipped to the General Electric Company's Philadelphia works for inspection and preliminary operating tests under no-load conditions, and then it was installed for testing at the J. D. Ross substation (Vancouver, Wash.) of the Bonneville Power Administration. The tests were made on February 22, 23, and 24, 1947, and, in keeping with the fundamental purpose of the tests they were witnessed by representatives of several circuit breaker manufacturers and by many operating engineers from different parts of the United States.

Paper 48-43, recommended by the AIEE switchgear committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26-30, 1948. Manuscript submitted November 17, 1947; made available for printing December 16, 1947.

ALEXANDER DOVJIKOV is chief of analysis and research unit and CLIFFORD C. DIEMOND is chief of relay unit; both with the engineering division of Bonneville Power Administration, Portland, Ore.

We are pleased to acknowledge the valuable assistance of W. Borgquist, general director of the Royal Board of Waterfalls, Sweden, who supplied us with a copy of an instruction book for this circuit breaker, of H. L. Levinton, E. J. Harrington, S. Fry, and the group of oscillograph operators in preparing the test program and making the tests. The tests were made on a heavily loaded, very extensive system, and the work of the dispatchers under the direction of J. O. Swanson deserves special recognition.

General Information Concerning the AEG Free-Jet, Air-Blast Circuit Breaker

1. CIRCUIT BREAKER NAMEPLATE DATA

NR 611299-300-301
AEG Compressed Gas Circuit Breaker
Type *APF-2507*—220/600 A—50 Cycles
Series 220, Rated Voltage 220 Kv
Rated Current 600 Amperes
Short Time Current for 1 second—20,000 Amperes
Inrush Current —25,000 Amperes
Maximum Interrupting Current—8,500 Amperes
Maximum Interrupting Capacity: 3 poles–2,500 megavolt-amperes
Operating Voltage 220 Kv, at 18-20 Atmospheres
Closing Solenoid—220 Volts (Direct-Current)
Opening Solenoid—220 Volts (Direct-Current)
Short Circuit Trip Solenoid—220 Volts (Direct-Current)
General Plan—Number 0111537
Compressed Air Tank Nameplate—21 atmospheres, 570 liters

2. APPEARANCE

The circuit breaker, Figures 1 and 2, is composed of three poles, each pole consisting of two vertical porcelain columns

Figure 1. Circuit breaker in open position

Table I. Summary of Contact Millivolt Drop Tests

Contact Drop in Millivolts at 100 Amperes

Phase	On January 24	Immediately Before February 22 Tests	Following Test Number 7	Following Test 12-2
A	17.9	34	23	23.5
B	17	38	18	18
C	18	39	30	22

about ten feet high and separated by a distance of $8^3/_4$ feet. Each column has a radial disconnecting arm attached at its top. All columns are linked at the base in such a way that rotation of the columns causes the two disconnect arms to swing apart for circuit isolation. Each pole unit is mounted on a steel frame directly above a compressed air tank which is an integral part of the frame. The three compressed air tanks are connected together and to the source of high-pressure air. The normal operating pressure is between 18 and 20 atmospheres, or about 280 pounds per square inch. An operating piston mounted on the center phase air tank rotates all insulator columns simultaneously (through linkages) thereby providing opening and closing of the disconnect arms.

Perpendicular to the tip of each radial disconnect arm and extending horizontally is a retractable interruptor contact mounted in an arc extinguishing head, (Figure 3 and Figure 4). The arcing contacts are hollow cylindrical rods which protrude from the extinguishing heads into free air where they are butted together by spring action when in the closed position. High-pressure air is carried up through steatite insulating tubes inside the vertical porcelain columns and out through ducts to the extinguishing heads where it acts both to separate the contacts and to extinguish the arc. When retracted, the contact faces are shielded by a hard rubber nozzle on the extinguishing head which controls the arc and directs the arc-extinguishing air during interruption. The terminal connections are located at the top of each porcelain column and are connected directly to each disconnect arm by means of a slip joint. To prevent the condensation of water inside the insulator columns, a small quantity of low pressure, dry air is circulated continuously in and around the steatite tube in the column.

3. Control System

Figure 5 shows the schematic of the pneumatic control system, and Figure 2 represents the isometric drawing of the circuit breaker with its air system. Other than functions of the tripping and closing solenoids and various mechanical interlocks, all operations are performed pneumatically with pneumatic seal-in until completion of the circuit breaker operation. The nominal operating pressure of the circuit breaker air system is 285 pounds per square inch (20 atmosphere). Minimum operating pressure is 256 pounds per square inch as indicated on the circuit breaker and by drop out of a low-pressure relay located in the circuit breaker control circuits. In order to overcome the toggle and buffer springs, a minimum of about 180 pounds per square inch is necessary for a 3-phase full-open operation. The circuit breaker requires 175 pounds per square inch to completely close from the full-open position. Interrupter contacts retract at a minimum of 60 pounds per square inch.

A. *Three-pole closing* from the full-open position of the disconnect arms may be initiated by either energizing the "close solenoid" or by manually applying high-pressure air from the main reservoir to the close holding piston through an external hand-operated valve (not shown). Motion of the solenoid plunger is transmitted through a linkage to open the "close valve," which permits the high-pressure air to flow from the air reservoir to the main operating piston. The insulator columns and disconnect arms are caused to rotate until full closure is obtained. No operation of the blast valves and interruptor retractable contacts occurs during closing.

Seal-in, until complete closure, is obtained by introducing air from the downstream side of the close valve to the "close" holding piston. Seal-in is continued until full closure of the circuit breaker when the disconnect operated rocker arm opens the ball valve below the "close" holding piston. Solenoid current is interrupted by mechanical auxiliary switches.

A typical closing time as measured from coil energization was 36 cycles (0.6 second) with an accompanying drop in air pressure of about 5 from 285 pounds per square inch.

Air remaining in the main operating piston and line is exhausted to the atmosphere through ports in the circumference of the piston cylinder.

B. *Three-pole, full-open tripping* is similar in initiation and seal-in to the corresponding features of the closing operation.

Air from the full-open trip valve is fed directly to the single-phase blast valves on the outer phases and through the opening piston control valve to the blast valve on the center phase. This air causes the blast valve main piston to open a valve which permits the passage of high-pressure air directly from the main reservoirs to the interrupting heads on each phase. As the central phase blast valve main piston moves down, a port is uncovered which allows the air to flow back to the top of the opening piston control valve.

This causes the opening piston control valve to open to admit air to the main operating piston. The foregoing sequence phase interruptors provide interruption of current before disconnect rotation is started by the main operating piston. After about 30 degrees of rotation, the disconnect-operated cam and its associated interlock piston cut off the air from the opening piston control valve causing the blast valve to reset, thus cutting the high-pressure air from the interruptor heads. Any high-pressure air left in the blast valve is quickly exhausted to atmosphere through the air relief valve as the blast valve piston resets.

Typical times for this type of operation varied from 7.5–8.0 cycles as measured from energization of the solenoid to the time of contact parting. The corresponding pressure reduction averaged 35 pounds per square inch for this 3-phase operation. The disconnects were fully open in about 35–40 cycles.

C. *The single-phase, short-circuit tripping* is arranged to provide high-speed, single-phase or 3-phase reclosing.

Operation of the corresponding trip solenoid as determined by the external phase selecting protective relays admits air from the reservoir to the holding piston, the pneumatic delay chamber, and the single-phase blast valve of the appropriate phase or phases. The blast valve function is similar to that previously covered except that air is not fed back to the opening piston control valve to cause disconnect rotation. The interruptor contacts are held in the retracted position by air from the blast valve for a definite period. This period is determined by the length of time required to equalize pressures on both sides of the holding piston. Equalization takes place through a small reducer and the pneumatic delay chamber.

Contact parting time varied from 3.5 to 3.7 cycles with a pressure reduction of about 6 pounds per square inch for a single reclosing operation of one phase. The contacts remain open for a minimum of about 11 cycles before reclosing. Reducers were prepared which would permit reclosing in about 15, 20, and 25 cycles, as measured from trip coil energization to the time at which the contacts first touched on reclose. Actually during the reclosing fault tests, the circuit was reestablished by arcing about two or three cycles before the contacts touched.

Provision is made for interruption of solenoid current by air-operated auxiliary switches.

Relaying and Electrical Controls Used for Test

Relaying for the single-phase reclosing tests was provided by instantaneous overcurrent elements, one for each phase. A special timing and auxiliary relay circuit was arranged. This circuit energized all four trip solenoids to provide blast action and disconnect full open operation if the fault was re-established on reclosure. Current for the four solenoids was interrupted by circuit breaker operated auxiliary switches. The first fault for any reclosing test would be interrupted by operation of the solenoid of the faulted phase, single-phase short-circuit trip valve, and the faulted phase blast valve.

Relaying for 3-phase reclosing tests was arranged so that the three single-phase short-circuit trip solenoids were paralleled for the first fault. On reclosure, if the fault was re-established, the "full-open" trip circuit solenoid was paralleled with the three solenoids.

Three-phase nonreclosing relaying was arranged so that all four trip solenoids were energized simultaneously by any one of the fault overcurrent relays.

The 3-pole tripping arrangement with which the circuit breaker was equipped was found during preliminary tests to introduce about two cycles of more delay in opening the circuit breaker than the single-pole operation. Therefore the control wiring for the tests was arranged to parallel the three single-pole trip circuits and the 3-phase trip coil during 3-pole circuit breaker operations.

4. Retractable Contacts

The retracting contacts of the AEG air-blast circuit breaker are hollow copper rods with an outside diameter of $1^1/_8$ inches and an inside diameter of 5/8 inch. Spectrographic analysis indicated that the tips were predominantly pure copper with traces of lead and tin (which may have been extraneous impurities). The contact rods are screwed into the operating piston assemblies and may be easily interchanged.

During the lower fault-current tests on the circuit breaker, the outer edges of the tips were found to have slightly mushroomed out due to impact during circuit breaker closing operations. This swedging action had increased the tip radius by approximately 1/16 inch after test 11, at which time they were dressed down.

As the fault currents increased, the inner surface of the tips began to assume a funnel shape presumably caused by the hot arc, the products of which were blown back through the contact rod to the baffle plate at the rear end of the interruptor. Examination of this baffle after the test showed traces of molten copper deposited on the baffle plate.

In spite of the distortion of the contact tips the conductivity between the contacts remained as good as at the start of the test. Preliminary checking of the circuit breaker during mechanical operating tests indicated that with 100 amperes applied across the contacts an average voltage drop of 18 millivolts was measured. Just before the actual fault tests (and after the contacts had been well lubricated) the average voltage drop was 37 millivolts; after test 7 the average drop was 20; after test 16 the drop was 21; and at the conclusion of the tests the millivolt drop was of the same magnitude. These figures compare favorably with typical values of 25–35 and 40–50 millivolts at 100 amperes for two types of 230-kv circuit breakers of American manufacture.

Since the later high-fault current tests were conducted only on the *A*-phase pole,

Figure 4. Cross-section of the interruptor

the duty on the A-phase contacts was relieved by the interchange of the C-phase contacts following test 31, at which time the contacts were again dressed down. This operation took less than 30 minutes. See Table I.

General Test Program

1. Fault-current interrupting tests were made to determine the ability of the circuit breaker to interrupt 3-phase-to-ground and single-phase-to-ground fault currents within its rating, and the time required for interruption. The effect of air pressure on the ability of the circuit breaker to interrupt fault currents and on the speed of interruption was also covered within the permissible range of operating pressures. The tests were started with currents approximating 20 per cent of the circuit breaker rating, and the current was increased in steps as permitted by system connections; the maximum current value being limited by the system capacity at the test location.

2. Reclosing tests were made to determine the suitability of the circuit breaker for both 3-pole and single-pole, high-speed reclosing duty especially for 20-cycle or faster reclosing. These tests also started with lower current values which increased as the tests progressed. Determination of the fault-arc deionizing time for the various current values was considered to be an important by-product of these tests inasmuch as the deionization time determines how rapidly reclosing may be permitted to take place without re-establishing the fault arc for nonpermanent faults.

3. Line-charging current switching tests were made to determine the suitability of the circuit breaker for this service. Particular attention was given to restriking and to overvoltages produced by such restriking. The effect of current magnitude was covered by using two transmission lines having lengths of 71 miles and 169 miles, respectively.

Measurements

The various quantities affecting the performance of the circuit breaker were recorded by means of electromagnetic oscillographs. To obtain a more detailed voltage record (and to check voltage records on the electromagnetic oscillographs) voltage of one phase was recorded by photographing on moving film the screen of a sealed cathode-ray tube. In addition, a Western Electric Fastax camera capable of taking 16 millimeter motion pictures at 4,000 frames per second was used to photograph the operation of the AEG circuit breaker. Projection of the pictures at the normal speed of 16 frames per second produces slow-motion pictures with time expansion of 4,000/16 or 250 times.

Results of the Fault Current Interrupting Tests

The data obtained from the oscillograms are summarized in Tables II and III. These show that, with line-to-line bus voltages of 207 to 210 rms kilovolts, the circuit breaker interrupted fault currents in from 3.8 to 6.5 cycles with the majority of the faults being interrupted in from 5 to 6 cycles. Figure 6 represents a typical oscillogram of opening 1,300 megavolt-amperes of the 3-phase-to-ground solid fault. The circuit breaker successfully interrupted all faults except during one test (number 5) covering a 3-phase arc fault with 15-cycle (American Standards Association, ASA, definition) reclosure. For this test, phase C failed to interrupt during the second interrupting operation and the fault was cleared by the backup circuit breaker. No reason is known for the failure of the circuit breaker to interrupt fault current on this operation.

No noticeable difference was observed between the first and second operation during reclosing tests. When interrupting the higher value of fault currents, the contact arc exhibited a more flaming characteristic. Examination of the high-speed motion pictures taken during these tests corroborated this visual observation and disclosed some tendency of the arc to flare radially for distances approximating the diameter of the arc head. It is of interest to note that the heavier fault currents required somewhat less time to interrupt than the lighter values of fault current. For fault values ranging from 1,600 to 2,100 megavolt-amperes, the circuit breaker interrupted within 5.4 cycles except for test 29 (a close-open operation at 2,100 megavolt-amperes) which required 5.8 cycles from trip energization to interruption.

The 3-pole arc fault reclosing tests show two unsuccessful reclosures (fault arc re-established after reclosure) where the dead time between the end of the first interruption and the re-establishment of the cir-

Notes:

1. Reclosing time is nominal time from first trip coil energization to contact touch on reclosing.
2. All times in cycles on 60 cycles-per-second base.
3. Time from second trip coil energization to tripping of backup circuit breaker (none taken before Test 11).
4. Rms fault current $= \sqrt{AC^2 + DC^2}$; taken for circuit breaker at 3.6 cycles after trip coil energization (approximate time of contact parting); taken for fuse at start of arcing.
5. Fault megavolt-ampere $= \sqrt{3}$ (bus voltage) (Highest phase-current).
6. Melting link for fuses was cut; therefore interrupting time does not include time of melting link.
7. Current values not obtained—No "A" oscillogram.
8. Dead time indeterminable from oscillogram.
9. Low value attributed to current-transformer saturation.
10. This period includes a period of capacitive-coupled current flow. See discussion for this test in results.
11. Restrike on *A* Phase.
12. Successful reclosure.
13. *C*-phase failed to open on second interruption, *B*-phase restruck for one-half cycle on second interruption. Unsuccessful reclosure.
14. Unsuccessful reclosure.
15. Unsuccessful reclosure. Backup circuit breaker cleared second fault.
16. Fuse failed to clear fault. Current fully offset.
17. Backup circuit breaker cleared second fault.

Figure 6. Test 7-1: Solid fault 3-phase-to-ground at Ross substation. Operation: open. Calibration in instantaneous values

cuit was of the order of only six cycles (tests numbers 5 and 6, Figure 7). Two additional tests, numbers 4 and 8, having a dead time of the order of 12 to 14 cycles resulted in successful reclosure indicating that the minimum possible deionizing time of a fault arc across a 16-unit insulator string may range between the values of 8 and 12 cycles. The single-pole reclosing tests are believed to be even more interesting. In the majority of these tests a 71-mile transmission line was energized from the Ross Substation with the fault applied to one conductor of the single-circuit transmission line. Operation of the air-blast circuit breaker served to disconnect only the faulted phase from the Ross bus. This phase, however, remained capacitively coupled to the two energized unfaulted phases. Unfortunately, the current transformer which had been connected in the fault circuit, to show the fault current continuity as a consequence of the capacitive-coupling current after the circuit breaker operation, was flashed over by the fault arc, thereby effectively short circuiting it so that records of the coupling capacitive arc current were not obtained. However, a second indication of the presence of such capacitive current was provided by the high deflection galvanometer connected to record the voltage across the arc path. This galvanometer showed a changing voltage during the periods of capacitive coupling current in accord with the inverse current-voltage law of arcs in a gas; in addition this voltage is nonsinusoidal during the passage of the capacitive coupling current through the fault arc path and becomes sinusoidal with the cessation of such current flow. In test 9-2 (Figure 8), the 13.7 cycles between the end of the first interruption and the re-establishment of the circuit consisted of approximately 11.2 cycles of capacitance follow current and of approximately 2.5 cycles of time during which no current flow occurred. At this point the circuit breaker contacts were reclosed, and the fault path withstood normal voltage for approximately 0.1 cycle (as shown on both the electromagnetic and cathode-ray oscillograms) following which the system voltage reached a point sufficient to break down the inadequately deionized arc path to re-establish the fault. During the remaining single-pole reclosing tests the time between the interruption and reclosure was increased approximately 18 cycles, and three tests with successful reclosure were performed.

** Approximately 2 1/2 cycles of zero current between first and second restrikes.

Figure 8. Test 9-2: Arc fault phase *A* to ground at Ross substation. Operation: Open *A* phase-close-full open. Calibration in instantaneous values

These values indicate that, at least for the circuit conditions used, 14 cycles between interruption and reclosure is insufficient to ensure that the arc path deionization will proceed to a point adequate for withstanding the system voltage; whereas 18 cycles provided the necessary additional time for the path to deionize sufficiently. The high-speed motion pictures definitely show the presence of current in the arc path following circuit breaker opening, a thin-cored arc being visible after the cessation of the main fault current within the luminous gasses which had been produced by the main fault arc. The pictures for test number 9-2 shows the continuous presence of this thin-cored arc between the end of the first fault current interruption and the re-establishment of fault current by the circuit breaker reclosure. Although the few tests which were made are not considered conclusive, they confirm data obtained by the Bonneville Power Administration from similar tests at lower fault current values.

Although the Bonneville Power Administration in some previous tests of single-pole reclosing has successfully reclosed 230-kv circuit breakers in approximately 12 cycles between interruption and reclosure, the duration of the capacitive-coupled current was of the same general order as during this series of tests. Consequently, pending the acquisition of more data, it is our belief that where single-pole reclosing is employed, for power fault currents ranging between 600 and 5,000 amperes and for conventional 230-kv lines, a minimum of 17-20 cycles must be allowed between the interruption and reclosure to ensure successful reclosure. The difference in the time between interruption and reclosure of 17-20 cycles for single-pole reclosure and 8-12 cycles for 3-pole reclosure is due to the effects of the capacitively-coupled current encountered in single-pole reclosure.

The low deflections necessitated by the narrow film used with the cathode-ray oscillograph was not conducive to accurate determination of the rate of rise of the recovery voltage following a fault. Measurements under similar test conditions give values ranging as low as 200 volts per microsecond and as high as 1,000 volts per microsecond; the differences were seemingly caused by the instantaneous value of voltage toward which the system was rising at the moment of interruption. The majority of measurements of rates of rise of recovery voltage resulted in values close to 450 volts per microsecond. The results of the fault tests are summarized in Table II.

Results of the Line-Charging Current Interruption Tests

The interruption of line-charging current by the AEG circuit breaker resulted in numerous "restrikes" at the half-cycle points both with the 71-mile line and the 169-mile line. Restrikes were not counted prior to a zero current period of at least one-quarter cycle, all previous current discontinuities being classed as arcing. Furthermore, the restriking was not restricted to the period normally ascribed to current interruption by the circuit breaker, that is, during the time of operation of the blast valve and retraction of the contacts within the interrupting heads, but continued for periods of column rotation for isolation up to approximately nine per cent of rotation.

Due to the large number of restrikes at the half-cycle points, only three such tests were made; two tests on the 71-mile line and one test for the 169-mile line.

Test 18-2 (Figure 9) with 71 miles of line had seven cycles of restriking with 10 restrikes on phase *A*, three restrikes on phase *B* (two of which occurred after a lapse of $2^1/_2$ cycles), and 14 restrikes on phase *C*. Four of the phase *C* restrikes occurred after the columns started rotating so that about 6 per cent isolation was achieved before line-charging current interruption was completed. The maximum line overvoltage was produced at the next to the last half cycle. It was measured as 2.8 times normal on the cathode-ray oscillograph record and only 2.3 times normal on the magnetic oscillograph record. This discrepancy was naturally expected.

Test 23-2 with 169 miles of line had seven and one-half cycles of restriking with 12 restrikes on phase *A*, of which three occurred during disconnect movement amounting to about five per cent of its travel, five restrikes on phase *B* before disconnect movement, and 13 restrikes on phase *C*, of which five restrikes occurred during disconnect movement amounting to about nine per cent of its travel at the end of which the retracted contacts were separated by a distance of 20 inches. A potential transformer connected to phase *B* at North Bonneville substation, 36 miles out on the line being switched, is believed to have been of assistance to the phase *B* interruption by draining a portion of the charge from the phase-*B* line conductor so that restriking on this phase took place for only $2^1/_2$ cycles. A slight indication of low-frequency oscillation such as takes place between line capacitance and potential transformer inductance which saturates in the presence of the line charge is shown on the line voltage record for phase *B*. Maximum overvoltages during this test were measured on the cathode-ray oscillograph connected to record the phase-*C* voltage to ground of the line as 2.9 times normal and on the electromagnetic oscillograph as 2.5 times normal on the next to the last restrike for phase *C*.

Test 9. Test 18-2: Line to Chehalis, 71 miles. Operation: Open line charging current 48 amperes. Bus voltage 209 kv. Calibration in instantaneous values

The high-speed motion pictures corroborate the movement of the isolating disconnects before current interruption during test 23-2. This was the only test showing this effect for the phase-*A* pole of the circuit breaker, the pole which had been chosen for photographing.

Oscillograms also were taken during two line energization tests. No unusual phenomenon or overvoltage are shown on the records. Likewise, during all the line-switching tests, disturbance to the bus voltage was practically zero. The results of line-charging current interruptions are summarized in Table III.

Discussion and Conclusions

Examination of the results shows that the tested AEG circuit breaker interrupts 60-cycle fault currents within its rating in from 5 to 6.5 cycles (0.08 to 0.108 second). Preliminary tests showed that close to 3.6 cycles (0.06 second) were required to part the contacts leaving an arcing time of 1.4 to 2.9 cycles.

The question arose as to the evaluation of the nameplate interrupting capacity of the tested circuit breaker (2,500 megavolt-amperes). According to the German standards (VDE Std. number 0670, November 1941, Par. number 39):

"The nominal interrupting capability of the circuit breaker in which the minimum time between the trip impulse and the separation of contacts is equal or longer than 0.1 of a second must be proved only on the basis of symmetrical interrupted current. In such cases the unidirectional component of the short-circuit current at the moment of contact separation must not exceed 20 per cent of the peak value of the a-c component.

"For circuit breakers in which the time is shorter than 0.1 of a second, the nominal interrupting capability must be proved also on the basis of asymmetrical interrupted current. In this case the unidirectional component of one phase must be at least 50 per cent of the peak value of the a-c component."

In departure of this rule, however, the calculations of interrupted megavolt-amperes in this report were made in conformity with the present ASA Standards, that is, on the basis of the measured asymmetrical value of current at the moment of contact separation. The reasons for this method of calculation are:

1. The tests were made to determine the characteristics of the circuit breaker when used on an American system and therefore a common basis of comparison with an American-made circuit breaker should be used, and the use of the ASA definition would result in data of greater use to American engineers.
2. In the various tests the times of interruption were both greater and less than the 0.1-second demarkation time of the German standards covering the effect of asymmetry.
3. The tests were made at 60 cycles, whereas the circuit breaker has a 50-cycle rating.

Although the time required for 2-fault interrupting operations at 500 megavolt-amperes was longer than 6 cycles, the circuit breaker in its present form is believed to be a 6-cycle (0.1 second) circuit breaker with 0.06 second required to part contacts (dead time) and 0.04 second of arc interruption (arcing time). Both components of the total interrupting time are longer than in the fastest circuit breakers of American manufacture.

Shorter dead time appears possible if the blast valves can be located closer to the interrupting heads thereby decreasing the transit time of the air to the heads and by improvements in control such as greater use of direct-acting electrical controls rather than slower operating pneumatic controls. More rapid retraction of the contacts into the interrupting heads also may be possible. A dead time of 1.5 to 2.0 cycles or even shorter may be feasible.

Improvement in arcing time may be more difficult to obtain, as the contacts must be retracted from a region of atmospheric pressure to the pressure conditions present within the interrupter heads. Inspection of the construction of the interrupter heads leads to the question of whether the interrupter construction results in the arc being drawn into a region of high-pressure air. Such action would be very desirable in order to use the excellent insulating property of high-pressure air. Better interrupter-head design, making this possible, and possibly more rapid contact movement should result in a considerable decrease in arcing time and a smaller deviation than the 1.5 cycles found in the arcing time required during the tests. The characteristics of the circuit breaker while interrupting line-charging current are considered particularly poor in view of the comparatively low-line voltage (207 to 210 kv) of the tests. The lengthy restriking period at the half-cycle points, while not producing serious overvoltages during the tests, is considered objectionable. The difficulty of the circuit breaker to interrupt line-charging current, as shown by disconnect operation before interruption coupled with the restrikes recorded on the oscillograms obtained lead to the opinion that such interruptions are tantamount to a plain break in air. Again this points to possible improvement of interrupter-head design to obtain the insulating qualities of the high-pressure air available with air-blast circuit breakers.

The limitation of overvoltages during line-charging current interruption tests to less than three times normal is attributed in part to corona effects which quickly lowered the trapped voltage on the line being switched as is shown on the line voltage traces of the line-drop test oscillograms.

The data obtained on arc deionization are believed to be of considerable importance. For 3-pole reclosing it indicates that the minimum dead time, during which fault arc current must be completely interrupted at both ends of a circuit, cannot be less than eight cycles and may be longer before successful reclosure can be assured. Even for the less favorable conditions, where interruption of fault current at the far end of a long line connected to a complex system may require from 8 to 10 cycles, the possibility exists of successful 20-cycle, 3-pole reclosure. However, if low-ohmic series resistors are included in the construction of a circuit breaker, the total time of resistor current, both immediately following the opening of the circuit breaker and immediately preceding its reclosure, must be added to the minimum permissible fault deionization time in order to ensure successful reclosure. Nonsimultaneous relaying on the longer lines will also serve to lengthen the permissible minimum reclosing time.

Single-pole reclosing was shown in the results to probably require from 17 to 20 cycles for arc deionization alone because of capacitive coupling of the faulted phase with the unfaulted phases. Here again the presence of series resistors in the circuit breaker may necessitate a further increase in time to allow for the periods of resistor current. Since both the coupled current and the resistor current are small compared to the fault current, and since for at least a portion of the period between interruption and reclosure they flow simultaneously, the total time of resistor current flow may not add directly to the 17-20-cycle deionization time believed possible for circuit breakers without resistors.

In light of the foregoing, we consider present circuit breaker standards to be insufficient for defining the interrupting time of circuit breakers equipped with low-ohmic resistors. We urge that additional data be secured whenever possible to more conclusively establish the deionizing time of power fault arcs.

The AEG air-blast circuit breaker does not approach the best of American oil circuit breakers in speed of fault-current interruption, in the ability to interrupt line-charging current with little or no restriking. However, the simplicity of the AEG circuit breaker, its ease of maintenance, freedom from use of oil, oil maintenance and handling requirements, freedom from fire, and its general performance evoked wide-spread interest among all observers. It is believed that its controls and the interrupting heads can be modified to approach American standards without sacrificing basic simplicity, and other advantages of the AEG circuit breaker. In order to clarify the necessary modifications, additional tests are considered necessary.

Some of the Proposed Additional Tests

1. One of the most interesting features of the tested circuit breaker is that even for 220 kv a single break is employed, whereas the designs of other manufacturers use a multibreak principle. It is considered desirable to test this entire circuit breaker as a single-pole circuit breaker with two and three poles of the circuit breaker in series to represent multibreak action and to establish in this way any advantages that multibreak may have over a single break in the speed of fault-current interruption and in decreasing restriking during the interruption of line-charging current. The use of resistors with the circuit breaker should also be investigated.
2. As the maximum faults at the J. D. Ross substation were limited to about 2,100 megavolt-amperes (ASA definition) and were cleared by the tested circuit breaker without difficulty, it is intended to test the circuit breaker at Grand Coulee where heavier faults, well above circuit breaker rating, may be established.
3. Testing this circuit breaker from an isolated Grand Coulee bus (with no lines connected) will provide a higher rate of rise of recovery voltage than at J. D. Ross substation. For the same purpose, 3-phase faults will be ungrounded.
4. It is intended to investigate the possible improvement in circuit breaker operation resulting from the use of special alloys for the tips of the retractable contacts.

These proposed tests by the Bonneville Power Administration have been indefinitely deferred because of budgetary limitations.

This circuit breaker in its present form will be installed in the Bonneville Power network for observation of its characteristics in actual service.

Discussion

R. Willheim (201, Clive Road, London, S.E. 21, England): The presentation of the design which is the subject of the present paper has, from a formal aspect, an unusual feature. It is a report on field tests performed on a circuit breaker not submitted by its manufacturer, and carried out without competent representatives of the firm having a chance of tendering advice. The authors must be complimented on the very fair and tactful approach and the most efficient way in which they have discharged their delicate and difficult task. The writer feels entitled to these comments in view of the fact that the first version of the 230-kv free-jet circuit breaker was developed before 1937 at which time he resigned from his post as chief electrical engineer of the section of the AEG works manufacturing high-tension equipment. Out of the old team he would appear to be the only senior member living outside Germany. He thinks that by contributing to a number of points raised by the authors he may achieve the double purpose of serving the art and enhancing the recognition due to the pioneers of a new technique.

The first 110-kv air-blast circuit-breaker was completed in 1929, and the first 220-kv type was commissioned in 1934. Using a single break up to 110-kv inclusive, the "candle types" in which these early efforts crystallized were characterized by a closed arc chamber incorporating a metal nozzle of large diameter, $1^1/_4$ inches. As soon as the tip of the tapered pin at the end of the contact rod was withdrawn, it immediately passed into the zone of most effective blast. At the same time, a suitable clearance from the large surrounding orifice was established. The arc duration did, therefore, not exceed one cycle. Bulky design, large moving masses, and considerable air consumption were the price to be paid for this performance. A two-stage alternative with two nozzles of smaller diameter appeared to offer little, if any, gain in economy, simplicity, or air consumption. Subsequently an insulating nozzle was adopted utilizing the discovery that, while none of the inorganic insulating materials available at the time would withstand arc temperatures, certain organic materials, rubber in particular, are self-protecting due to very thin surface layers becoming volatilized when in contact with the arc. The moving contact

fills the throat of the insulating nozzle, thereby blocking the air flow until the contact tip is withdrawn past the narrowest cross section. Several half cycles pass in this way during which the arc is drawn in still air. The arc energy remains negligibly small, and oscillographic records hardly reveal any trace of arc voltage. As soon as the orifice is free and the air flow is established, the whole length of the already existing arc column is exposed to its scavenging action, with the arc root being positioned so as to be subject to the most effective combination of pressure and velocity. It was, of course, realized that this solution was a compromise, putting simplicity, ease of mechanical operation, and air economy before minimum over-all operating time. It should not be overlooked that in Central Europe, with practically all transmission systems resonance grounded, there is virtually no stability problem and no demand for utmost reduction of the fault duration. True, the interruption of line charging currents at the first current zero, an important asset of the metal nozzle type, had also been sacrificed. A number of interruptions and restrikes would inevitably precede the final extinction of the charging current, but no cumulative overvoltages were anticipated in view of the low dielectric strength of the air gap during this period. In 1935 the writer had an opportunity of carrying out a series or such tests with the 220-kv air-blast circuit-breaker in Chevilly after it had been modified into a single-break candle type with insulating nozzle. Only one line was connected to the 220-kv bus bars. The arc duration did not exceed six half cycles (referred to 50 cycles), and was not disappointingly long if compared with the performance of an oil circuit-breaker of the dead-tank type with explosion pots, requiring 13 half cycles.

The Chevilly type, 30 feet high, was succeeded by a double break design for 220 kv, only 18 feet high, with internal capacitive control of the voltage distribution, Figure 1 of the discussion. Reduction of the stroke was obtained by shielding the contacts, and in particular withdrawing the movable contact behind a spherical metal screen. As in this way the internal insulation had become superior to the external insulation of the shortened interrupting chamber, the latter was supplemented by a series isolator. To understand the subsequent technical development it is necessary to appreciate the then prevailing situation. The power supply companies, while most apprehensive of the use of great quantities of oil in extra-high-tension circuit-breakers, were not prepared to pay higher prices for an oilless design. Competition with small-oil-volume circuit breakers was also intense, amounting to a feud between manufacturers of different persuasion. A further target was set by the demand for circuit-breaker types up to 220 kv transportable on railway trucks in completely assembled state ready for immediate service.

These were the conditions from which the free-jet circuit breaker originated, partly an austerity type and partly an inspired venture; it took its name from the German denotation for impulse water turbines. The design has been admirably described by the authors. Within the scope of this discussion the numerous details of pneumatic equipment, which were the accumulated results

Figure 1

of ten years development and operating experience, must be passed over, foremost among them the design of the blast valves and the choice of material for the valve seating. In electrical respect the arrangement under consideration differs from that known to the writer (design stage 1937) inasmuch as it employs hollow contacts and abandons the use of weather exposed cup-shaped ebonite heads moulded around a metal core consisting of spherical stress control shields. The following comments refer to points raised by the authors.

The interrupting device is more accurately described as a single-stage double blast arrangement. It is designed to interrupt cross-country faults in systems with ungrounded or resonance grounded neutral in which case one pole is subject to a recovery voltage of 220 kv.

While tungsten tips were found useful with contacts of the male and female type, ordinary copper would appear to be more suitable for butt contacts. The problem of erosion should not arise for the moderate short-circuit currents of extra high voltage systems. To the writer's recollection after a few short circuit operations the voltage drop of special arc resisting alloys ceased to meet the requirements of current carrying contacts.

The authors have given a fair account of the critical performance of the circuit-breaker when interrupting line charging currents. It should be worth while to further investigate the causes of the prolonged arcing after the retractable contacts have been fully withdrawn. In the writer's own experience with the first circuit-breakers of this type the period during which the contact clearance acts as a safety gap was always followed by speedy final extinction. As regards ultra-short interrupting times, there is no inherent limitation in the circuit-breaker design, and it has been explained before how, due to a different approach to the stability problem, this target did not arise.

To carry out tests with the three poles connected so as to form a multistage single-phase circuit breaker should not be expected to supply useful information unless the voltage distribution is controlled by considerable external means. In their final effect such means are equivalent to simply testing one stage at reduced voltage, whereas in fact the stroke should be reduced simultaneously.

Some may reject the free-jet circuit breaker as a "depression type," or condemn it by faint praise, others will hail it as a timely and most promising departure from a conventional technique. As in this unique case the inventor has no possibility to stand up for the development he has initiated, the writer feels it his duty to state that the credit goes to J. Biermanns, the man who has left his mark in every field of European high tension engineering, has revolutionized German transformer engineering, and has between 1926 and 1945 built up our present day air-blast circuit-breaker technique. He can be congratulated that against all previous opposition at home and abroad he could now see his principal ideas and basic designs becoming the foundations of a new art. In his latest creation, the free-jet circuit breaker, there are enough convincing features to look forward with interest to an improved balance of electrical characteristics.

Eric T. B. Gross (Illinois Institute of Technology, Chicago, Ill.): In comparing the performances of this air-blast circuit breaker of German origin and of oil circuit breakers for the same voltage which were built in this country, one should keep in mind that the German circuit breaker was built eight years ago (as the nameplate data indicate), which means that its construction is based on designs made in or more likely before 1939. Realizing that designs in the United States have been considerably improved during the past ten years, one must agree with the authors' conclusions that the many apparent advantages of such a type of air-blast circuit breaker deserve widespread interest. Anybody who was either present at the tests, or had the opportunity to see the movie shown in Pittsburgh after the presentation of the paper will be highly impressed with the performance of so simple a circuit breaker construction.

I understand that this particular type of circuit breaker is based on Dr. J. Biermanns' inventions, and that the first circuit breaker of the free-jet type for 110 kv was built in about 1935. This type of circuit breaker is, therefore, a more recent design and it seems possible that further development, based on field-experience, will bring it up to present-day standards. It is very likely that some research was done after 1939 in the AEG switchgear works, and its circuit breaker and high voltage test and research laboratory, the results of which could be used also in further studies and development work.

Whereas this free-jet type air-blast circuit breaker is of comparatively recent design, the earlier AEG-type air-blast circuit breakers which were based on patents of the late Professor S. Ruppel were first put into practical use in about 1928 (long before Hitler's days), and had reached standardization by 1932. This fact is of interest because it indicates clearly that technical considerations and not political pressure brought about the elimination of

oil from circuit breakers for all voltages. This German development was followed by the large manufacturers in most European countries, and we learn that one of the large manufacturers in Switzerland has already discontinued to produce any type of oil circuit breakers.

The paper leaves the impression that representatives of the German manufacturer were not present to help with the assembly and the test of the circuit breaker; I am wondering if this assumption is correct, and if so, whether the authors feel that the tests showed the best performance which this circuit breaker is able to give. It should be of interest too to know where the circuit breaker was originally installed in Germany on the 220-kv system, and what duties it had to perform at that location (actual short circuit megavolt-amperes, interruption of charging current of how many miles of equivalent 60-cycle line, and so forth).

The authors deserve an expression of gratitude from the profession for their interest in this part of equipment; such tests provide invaluable information not otherwise available, and they indicate in which direction improvement of our present-day equipment can be expected.

Alexander Dowjikov and Clifford C. Diemond: We welcome very much the "missing link" of our presentation, namely, the history of the development of the tested circuit breaker, kindly contributed by Gross and Willheim. All during the tests we were sorry that the originators of this type of circuit breaker were not able to attend the tests. We are glad that one of the originators (Willheim) recognizes our "very fair and tactful approach and the most efficient way in which we discharged our delicate and difficult task" of testing the circuit breaker without competent representatives of the manufacturer. Unfortunately, we cannot even tell Gross when the circuit breaker was installed in Germany and what duties it had to perform at that location; we had to base our installation and tests on the basis of the nameplate data, on the instruction book for this type of circuit breaker which we were fortunate enough to obtain from our friends in Sweden, and on our own careful study and interpretation of functions of different parts of the circuit breaker. We believe that we obtained from this circuit breaker a quality of performance essentially equal to its maximum capabilities. We hope that the described tests witnessed by representatives of all circuit breaker manufacturers and many operating companies will bring to focus further development of this type of circuit breaker which has many attractive features even if in its present form it does not measure up to the performance of the best circuit breakers of American manufacture.

New Devices Derived From a Torque Balance Telemeter

W. H. BURNHAM
ASSOCIATE AIEE

Synopsis: The continued increase in remote indication of electrical and nonelectrical quantities in this country and abroad has taxed the ingenuity of the engineer to provide new systems and auxiliary devices to meet their needs. One of the better known devices used for remote indication of electrical and nonelectrical quantities is the torque balance telemeter. The successful use of this telemeter has suggested the development of two pieces of auxiliary telemetering equipment which greatly broadens the field of application for this telemeter as well as serving to augment the general field of telemetering. These new devices, known as the load injector and the converter, working in conjunction with the torque balance telemeter provide the additional functions of signaling, and the totalizing and integrating of a telemetered quantity.

Torque Balance Telemeter

SINCE THESE NEW devices are a modification of the standard torque balance telemeter, a brief review of this telemeter is a desirable approach to the explanation of these two devices.

The torque balance telemeter[1] is capable of telemetering several quantities such as power, voltage, current, or angular position. Each of these quantities is telemetered by converting the quantity to a proportional value of d-c milliamperes which is transmitted over wire lines to an indicating or recording milliammeter whose scale is marked in units of the measured quantity.

The torque balance telemeter is a type of servomechanism in which two opposing torques are used to achieve the proportionality between the measured quantity and the output current in milliamperes. Basically, the device contains an operating mechanism, a restraining mechanism, a photoelectric follow-up system, and a power supply. The operating mechanism will depend upon the quantity being telemetered. Figure 1 shows a functional analysis diagram[2] of the device for telemetering power. In this case, the operating mechanism, which is shown as the primary detector, is a wattmeter mechanism without the control spring. The restraining mechanism is a d-c milliammeter mechanism with very low torque lead-in spirals substituted for the control springs. Both mechanisms are connected to a common shaft which also supports a small mirror. A beam of light is reflected from the mirror onto two phototubes. The relative amount of light on the phototubes determines the polarity and magnitude of the d-c output from the power supply.

With no input to the operating mechanism, the beam of light is divided equally between the two phototubes and the d-c output from the power supply is zero. When the operating mechanism is energized, the common shaft turns and the light reflected from the mirror illuminates one phototube more than the other, which causes the power supply to produce an output current. Since the d-c output flows through the restraining mechanism, it will produce a torque on the common shaft which, by virtue of proper lead connection, will be opposite to that produced by the operating mechanism. The output current will increase until these two torques are balanced. For this condition, there will be a definite distribution of light on the phototubes which means a certain value of output current for a given value of watts input to the operating mechanism will be established. Figure 2 shows the mechanical arrangement of the instrument mechanisms.

Normal supply voltage variations and changes in effective output resistance do not appreciably affect the accuracy of the device, since the photoelectric follow-up system immediately corrects for changes in output due to these variations. For convenience of installation, testing, and flexibility, the torque balance telemeter is now always built in a draw-out case for either surface or semiflush mounting. Figure 3 is a front view of the telemeter mounted in the draw-out case.

Figure 1. Functional analysis diagram of a torque balance telemeter for telemetering power

Paper 48-44, recommended by the AIEE joint subcommittee on telemetering and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted October 29, 1947; made available for printing December 5, 1947.

W. H. BURNHAM is with the General Electric Company, West Lynn, Mass.

Torque Balance Load Injector

With the many telemeter channels associated with a power system, channel outages are sure to occur occasionally. When this happens it is very desirable to have the indicating, totalizing, and recording circuits function normally. It is also desirable to have a signaling system between the dispatcher's office and power stations to tell the individual generating stations what load they should be carrying. The effectiveness of this system is increased if alarm features are incorporated to call the station operator's attention to a change in required load.

These requirements are fulfilled by the load injector, which is essentially a manually adjustable d-c milliampere power supply with special features incorporated. The output of the power supply can be varied from 2 to 50-milliamperes and will remain substantially constant when once set, even with normal supply voltage variations or changes in the load resistance. This device can also be made having lower output ratings such as 1 to 25-milliamperes. Figure 4 shows a diagram of the device. Two major changes were made in the torque balance telemeter to produce this device. First, the power supply was redesigned to provide the increased output current; and secondly, the operating mechanism was replaced by two instrument control springs. By means of a gear linkage the control springs can be rotated by a knob on the front panel. The torque produced on the shaft by the springs produces the same results as any electrical operating mechanism and becomes the input. Except for this manual adjustment of the input, the operation is nearly identical with that of the torque balance telemeter.

Variations of plus or minus ten per cent in the supply voltage result in only a plus or minus one per cent change in output current. The maximum value of load resistance into which it will operate with full ouptut is 1,000-ohms, and the variation in output current throughout the range of 0 to 1000-ohms load resistance is less than two per cent of full scale.

Figure 5 shows the front panel arrangement of the control knob, power switch, and a reversing switch for selecting the polarity of the output current. It is intended to be used with an indicating milliammeter, as a guide to the operator in adjusting the output, so the output control is not calibrated. The device is mounted in a semiflush case with draw-out construction.

When a channel outage occurs, it is usually possible to telephone the generating station and obtain the load that should be telemetered over the faulty channel. Then the load injector is connected to the receiving end of the channel and its output adjusted to this value of load. This enables the totalizing and recording circuits to function properly.

As a signaling device, the load injector may be located in the dispatcher's office and the receiving instrument in a generating station. With the instrument scale marked in units of load, the dispatcher can indicate to the station operator what load he should be holding.

Torque Balance Converter

As previously mentioned, the output current of the torque balance telemeter representing the measured quantity can be indicated and recorded. However, when telemetering power, it is often desirable to know the amount of energy generated during a certain period. This information can be obtained only by using a planimeter on the recorder chart, or a similar method to multiply the average value of power by the time. A similar problem exists in obtaining an integrated reading of power flow over tie lines. Since tie-line power flow may be in either direction, it is necessary to integrate the area under the curve on each side of zero on

Figure 2. Torque balance telemeter for telemetering three-phase power showing the mechanical arrangement of the instrument mechanisms

Figure 3. Torque balance telemeter mounted in the drawout case

Figure 4 (above). Functional analysis diagram of the torque balance load injector

the recorder chart and multiply by the time to obtain the resultant value and direction of the energy flow. When telemetering power, a very common requirement is that a reading be transmitted that represents the total of several power sources. If the telemeter transmitter operates on the watthour meter principle, some means of producing watts in proportion to the totalized reading must be used to operate the transmitter.

To solve these problems and provide directly a continuously integrated reading of the quantity from the output of a torque balance telemeter, the torque balance converter has been developed. If a quantity can be expressed in terms of watts, it can be integrated with respect to time by applying the watts to a watthour meter. The converter performs the conversion of d-c milliamperes to single phase a-c watts. By applying these to a watthour meter, a continuously integrated reading of the original quantity is obtained. The converter, shown in Figure 6, consists of two components, the converter unit and an amplifier. The converter unit, which is mounted in a two-element watthour meter case with draw-out construction, consists of a polyphase wattmeter mechanism and a d-c milliammeter mechanism connected to a common shaft. The control springs are replaced with very low torque lead-in spirals. The amplifier is conventional except that the output stage

Figure 7. Functional analysis diagram of the torque balance converter

is designed to deliver power at a high current level, so it can be considered a current amplifier.

The general principle of operation is similar to the torque balance telemeter and load injector in that it is a servomechanism in which balanced torques determine the output for a given input. A diagram of the converter is shown in Figure 7. One of the wattmeter mechanisms is used as a variable ratio transformer. That is, the current coil is excited with its rated current and a voltage is taken off the potential coil. The magnitude and phase of this voltage depends upon the relative position of the potential coil with respect to the current coil. The other wattmeter mechanism is used as a watt restraining mechanism, and the milliammeter is the operating mechanism. The voltage induced in the secondary coil of the variable-ratio transformer is the input signal to the amplifier. The load on the output of the amplifier consists of the current coil of the watt restraining mechanism and the current coil of a single-phase watthour meter in series. Their potential coils are excited from the 120 volt a-c supply. The operation is as follows: With zero input to the converter, the variable ratio transformer has zero coupling and no signal is applied to the amplifier. Thus the output current is zero and no power is applied to the watthour meter. As in the torque balance telemeter, energizing the operating mechanism rotates the common shaft. This results in a signal being applied to the amplifier. The output current does two things. It produces rotation of the watthour meter disk, and causes a torque to be produced by the watt restraining mechanism in the converter unit. This torque will be opposite to that produced by the operating mechanism, by virtue of the proper connections to it. Therefore, the shaft will rotate until sufficient output current is flowing to establish a balance of these two opposing torques. When the balanced condition is obtained, a definite amount of power will be represented by the output current and the 120 volts supplied to the potential coils. If the input milliamperes to the converter is doubled, the output power will be doubled as the result of a new balance being established. The watt restraining mechanism may be considered a monitor of the watts output since it determines the magnitude of output current for a given value of milliamperes input to the converter.

The error that is introduced by the nonlinearity of the watt-restraining mechanism is held to a small value by limiting the angle through which the shaft turns to only a few degrees. Normal line voltage variations have little effect upon the conversion accuracy since the watt-restraining mechanism will adjust the system by changing the output current.

If the polarity of the input d-c milliamperes is reversed, the power flow to the watt restraining mechanism and the watthour meter will reverse. This reversing feature makes the converter very adapta-

Figure 5. Torque balance load injector showing the control knob, power switch, and reversing switch

Figure 6. Torque balance converter, consisting of the converter unit and an amplifier

ble to integrating tie line loads where power flow may be in either direction. The torque balance telemeter can be used in conjunction with the converter for this application since it also has this reversing feature. In this case two watthour meters with detents are connected in series so that each meter will integrate power flow in only one direction.

Progressive standardization has made the torque balance telemeter an attractive device for totalizing at the transmitting end of a telemeter channel. For this application, a torque balance telemeter may be connected to each generator through instrument transformers, for measuring watts or vars, and the outputs paralleled. The totalized d-c milliamperes can then be applied to the torque balance converter and the output watts applied to a watthour meter impulse type transmitter, such as those used in several of the present systems. Even when thermal converters are used at the transmitting end, the torque balance converter is applicable if used in conjunction with a self-balancing potentiometer, which is a device that converts d-c millivolts to d-c milliamperes with high speed of response without moving parts other than a galvanometer.

Conclusion

In this paper, two new auxiliary devices for use with the torque balance telemeter and other types of telemeters have been presented. It is expected that their use will help fill the needs in the expanding field of telemetering. The load injector, in providing a means of signaling and acting as a phantom transmitter should raise the efficiency of a telemetering system. At present, it is expected that the torque balance converter will find application as an integrating device and a means of transmitting a totalized reading, but this, by no means, exhausts the possibilities of this device in telemetering and associated fields.

Application of Bolometers at Microwave Frequencies

BOLOMETRIC METHODS for the determination of absolute power level have become established measurement procedures[1] for frequencies in the microwave region. By proper use of a bolometer, power from a microwave source may be directly compared with known power magnitudes from a d-c or audio-frequency source. The developed techniques utilize the temperature-resistance characteristics of the bolometer. The change in resistance of a bolometer element due to a change in power is independent of the type of excitation. Thus an unknown amount of radio-frequency power which results in a given change of resistance may be equated to a known quantity of audio frequency or d-c power which results in an identical change in resistance. The basic problem, then, is the design of low frequency circuits and instruments to accurately and conveniently measure small increments of resistance.

There are two general methods available for measuring this resistance change; both employ a Wheatstone bridge in which one arm is a bolometer. In one method the bridge is always maintained at balance; in the other it operates unbalanced. The basic bridge schematic is illustrated in Figure 1. With radio-frequency power absent, the bolometer resistance is varied by adjusting the power of the biasing source until the bridge is balanced. The bolometer then is exposed to the unknown power supplied by the microwave source. This additional power causes a temperature rise which results in a change in the bolometer resistance with a subsequent unbalance of the bridge. When the unbalanced bridge scheme is used, the off-balance reading of the detector may be employed as the measure of the radio-frequency power, provided the indication of the null meter is calibrated against a known low frequency (or d-c) power increment. In another embodiment of this method, the change in bolometer resistance is measured by using variable calibrated resistors in the other branches of the bridge.

If the measuring system is to be operated as a balanced bridge, the incremental power source is adjusted for a null indication on the detector, and the increment of audio frequency (or d-c) power required to rebalance the bridge is a direct measure of the microwave power absorbed in the bolometer. Although the unbalanced bridge method may be a more straightforward procedure, in some respects it is inferior to the balanced bridge method. In a practical unbalanced bridge circuit a simple procedure must be devised for calibration; and the zero reset of the bolometer must be checked. Aside from these problems, a fundamental difficulty is that the bolometer resistance does not remain constant during the measurement process. This requires that the unbalanced detector be calibrated over its entire range of operation, and completely recalibrated when the bolometer ages or a new bolometer is used. In addition, the bolometer is used to terminate a microwave transmission line, and in broad-band power meters[2] the bolometer resistance is the most important component of the line termination. If this resistance is permitted to vary, the broad-band match may be affected adversely, and large errors due to reflection loss introduced.

The remainder of this paper is devoted to a discussion of balanced bridge methods in microwave bolometer power measurement which obviate some of these difficulties.

Balanced Bridge Methods

The bias supply for most bolometer bridge circuits is direct current. Such a source must have low inherent drift, for any change in bias level after the initial balance is introduced as an error in the measurement of the radio-frequency signal. The bias excitation may be provided by a rectifier power supply, but the requirements for low drift and high stability, and the need for relatively large bias currents, as in the case of high power bolometers (of the order of 100 milliamperes), make the design of such a supply somewhat of a problem. Furthermore, an instrument designed for field use will encounter a wide variety of main power sources, with poor regulation the rule rather than the exception. This array of difficulties suggests the use of an internal battery-operated bias supply. The bridge described in detail in this paper does in fact make use of a small storage battery supply with an output of 24 volts and weight of less than ten pounds. The ampere-hour capacity is large enough to permit normal operation of the bridge for about a month before recharging is necessary.

Manuscript submitted November 12, 1947; made available for printing December 11, 1947.

HERBERT J. CARLIN and JUDD BLASS are with the Microwave Research Institute, Polytechnic Institute of Brooklyn, Brooklyn, N. Y.

This work was done under contract W33-038-ac-13848 between the Microwave Research Institute of the Polytechnic Institute of Brooklyn and the Army Air Materiel Command Watson Laboratories.

As stated earlier, the incremental power source may be either audio frequency or direct current. In the former case the frequency must be chosen high enough to insure a period of oscillation which is fairly small compared with the thermal time constant of the bolometer. The audio oscillator must have high amplitude stability, and sufficient output to replace the maximum level of radio-frequency power absorbed by the bolometer. Output level may be measured with a vacuum tube voltmeter whose stability requirements are similar to those of the oscillator. At bridge balance the audio power into the bolometer of the bridge in Figure 1 is $v_a^2/4R_b$, where v_a is the output voltage of the oscillator and R_b is the resistance of the bolometer. If the vacuum-tube-voltmeter is to give a direct indication of the incremental power, the bridge arms must be compensated to give a true impedance balance. If an a-c high gain detector is used for a null indicator, the circuit must be carefully shielded and grounded to hold extraneous pickup to an absolute minimum. This is especially true if low radio-frequency powers of the order of 20 microwatts or less are to be measured with any degree of accuracy.

If a d-c incremental power source is used, it need not be physically separated from the bias supply but can be incorporated directly into the bias circuit. This consideration, with the elimination of the difficulties encountered with audio frequency when used in bolometer circuits, makes the all d-c bridge a very satisfactory instrument. Another advantage of the d-c bridge for field use is that no electronic tubes are needed.

The major advantage of an audio frequency substitution method is the orthogonality between a-c and d-c power in a resistor. That is, the total power is proportional to the sum of the square of the a-c current and the square of the direct current only. No cross product terms combining the a-c and d-c quantities are present. Thus the incremental power due to a change in audio current is entirely independent of the d-c bias level in the bolometer, and may be measured directly in the audio frequency circuit alone. This is not true, however, if the incremental power is direct current. In this case, the change in power is a function of the original bias level, and a knowledge of the incremental direct current alone is not sufficient to determine the true d-c power into the bolometer. This can be easily seen from the following expression for the change in d-c power, when the bolometer bias current I_b is changed by an amount ΔI.

Figure 2. Basic summation-type direct-reading wattmeter circuit

Change in d-c power

$$= P_{rf} = [I_b^2R_b - (I_b - \Delta I)^2R_b]$$
$$= [2I_b\,\Delta I - (\Delta I)^2]R_b$$

The bridge described operates as a balanced circuit, and is an all d-c instrument with self-contained battery pack. It therefore possesses the advantages associated with the elimination of an audio frequency oscillator and rectifier power supply. The presence of cross product terms in the expression for incremental power is taken into account by a specially devised circuit arrangement which permits the measurement of replacement power by a direct reading d-c instrument.

Bridge Operation

The total power dissipated in the bolometer at balance is fixed for a given bolometer. If the bridge is balanced by d-c power alone, and radio-frequency power is then introduced into the bolometer, the radio-frequency power is equal to the amount by which the d-c power must be reduced in order to effect a rebalance. Thus if the d-c bolometer current required for balance when radio-frequency power is absent is $I_0/2$, referred to as the bias current, and $I_1/2$ is the d-c bolometer current present at the rebalance after the addition of microwave power, the microwave power (P_{rf}) is

$$P_{rf} = \frac{R_b}{4}(I_0^2 - I_1^2) \tag{1}$$

This expression may be evaluated by determining I_0 and I_1 and subtracting their squares. A method like this suffers, however, from extreme inaccuracy when the power to be measured is small compared to the bias power, for then I_1 differs only slightly from I_0. Equation (1) may be rewritten as

$$P_{rf} = \frac{R_b}{4} I_0\left(1 + \frac{I_1}{I_0}\right)(I_0 - I_1) \tag{2}$$

Let the d-c power to the bridge be attenuated by the 4-terminal constant-input resistance network shown in Figure 2, so that the battery loading is constant, independent of attenuation. The difference $(I_0 - I_1)$, in equation 2 is the current flowing in the shunt branch of the attenuator. The sum factor, $[1 + (I_1/I_0)]$, is a parameter of the attenuator alone. Let

$$\frac{I_1}{I_0} = k$$

and

$$I_0 - I_1 = I_2$$

Equation 2 becomes

$$P_{rf} = \frac{R_bI_0}{4}(1+k)I_2 \tag{3}$$

The line current, I_0, is fixed for a given bolometer. R_b is the resistance of the bridge at balance. The microwave power is therefore linearly proportional to $(1 + k)I_2$.

In order to determine kI_2, a network consisting of an attenuator whose termination is a low resistance ammeter, is inserted in the shunt branch of the load attenuator. This network is ganged to the load attenuator, so that the k factors of both are equal for any attenuation setting of the network. The current I_2 can be measured by another ammeter in the shunt arm of the load attenuator. Rather than use two ammeters to obtain $I_2 + k\,I_2$, a double-coil instrument is employed which sums the currents automatically.

To make this instrument direct reading it is necessary to introduce the proportionality factor $R_bI_0/4$. This constant varies with individual bolometers due to manufacturing variations which preclude the same bias for each unit. The factor is essentially a meter scale constant and is calibrated for each bolometer by means of a variable shunt, R_B (Figure 2), across the double-coil ammeter. If the face calibration of the meter is W microwatts per milliampere and P_B is the ratio of the current in the meter I_m to the branch

current I_2 and if the meter is to read the power, the following must be true:

$$P_B W = R_b I_2/4 \tag{4}$$

The meter attenuator must be a constant impedance network in order that P_B be constant for all attenuator settings. The procedure used to calibrate the meter conveniently is described below.

Refer to Figure 2. L_1 and L_1' are the ganged load and meter attenuators. The input impedance at terminals $(a\text{-}a')$ is equal to R_b when the bridge is balanced. R_B is the calibrating shunt used to obtain the proper scale factor for the summation meter. A complete calibration and measurement procedure is as follows: with the attenuators out, the bridge is balanced by means of the "bias adjust" control R_0. The switches S_1 and S_2 are turned to position 1 and the current I_0 is measured with the differential ammeter now operating as a single coil instrument inserted in the line. The switches then are turned to position 2, and L pads are inserted whose attenuating factor k is determined by the equation

$$\frac{R_b}{4}(1-k_0^2)=1 \tag{5}$$

Since equation 3 may be rewritten

$$P=\frac{R_b I_0^2}{4}(1-k^2) \tag{6}$$

the setting, $k=k_0$, of equation 5, corresponds to the value which would be necessary to balance out a microwave power of I_0^2 microwatts. I_0^2 is known from the meter reading at the initial bridge balance. The calibration is accomplished by varying R_B, with $k=k_0$, until the summation meter indicates I_0^2 numerically in microwatts. The meter is now calibrated correctly over its complete range. The switches are set to position 3 and radio-frequency power may be introduced. The unbalance is now corrected by means of the L pad controls. At balance the meter reading directly indicates the absolute microwave power.

Figure 3. Equivalent bridge attenuator circuit including the metering resistance of R_B and R_M in parallel

The wattmeter model that has been built is designed to use a Wollaston wire element for low power measurement (0–1 milliwatt), and a metallized-glass element for high power measurement (10–100 milliwatts). The low power level is divided into two ranges, 0–100 microwatts and 0–1 milliwatts. The bias current is between 3 and 4 milliamperes. The calibration power, I_0^2 is about 50 microwatts. The calibration for this power level is made on the lowest range (0–100 microwatts) and holds true for the higher one (0–1 milliwatt). In the first range, 0–100 microwatts, I_2 never exceeds 100 microamperes. The range of the double-coil instrument is 200 microamperes and operates satisfactorily as an unshunted instrument for this part of the lower range. In the (0–1 milliwatt) range, I_2 may be as great as 1 milliampere, and the instrument must have a ten to one shunt across it in order that full scale deflection corresponds to 1 milliwatt. The design must take into account the fact that the load of the meter attenuator should remain constant for the calibration to be true for both the 0–100 - microwatt and 0–1 - milliwatt ranges. In the case of the metallized-glass bolometer the bias current is between 30 and 40 milliamperes, and I_0^2 is approximately 5 milliwatts. In order that the calibration point be at a reasonable scale position in the high power range, k_0 is chosen so that

$$\frac{R_B}{4}(1-k_0^2)=10$$

Bridge Design

A range of attenuation from 0.03 decibel to 3.0 decibels is needed to cover the limits of radio-frequency power to be measured. In order that accurate tracking be maintained between the load and meter attenuators, and that the two input impedances remain very nearly constant for all settings, it was advisable to design the attenuators as cascaded units consisting of resistors mounted on multiple point switches. The attenuations of the units are 0–2.7 decibels in 0.3-decibel steps, 0–0.3 decibel in 0.05 steps, 0–0.04 decibel in 0.01 steps, and 0.025–0.035 decibel in 0.001-decibel steps. The lowest steps of attenuation result in at most 1-microwatt steps for the low power bolometers and 1-milliwatt steps for the high power bolometers.

It is very important that the deviation of the input impedance from R_b be kept as small as possible. If I_0 is the line current at both balance and rebalance, and I_1 is the bridge current at rebalance, the power

Figure 4. Effect of meter resistance on wattmeter error as a function of attenuation for the uncompensated attenuator

$$a=\frac{\text{meter resistance}}{\text{bridge resistance}}$$

in the load is proportional to $(1+k)(I_0-I_1)$. If, however, the line current at rebalance has changed to $I_0+\Delta I_0$, I_2 then is equal to $I_0-I_1+\Delta I_0$. I_1 remains the same, as it must for the same microwave power. In the latter case the measured power is proportional to $(1+k)(I_0-I_1+\Delta I_0)$. Although ΔI_0 is small compared to I_0 it introduces a substantial error when considered as a part of the difference current I_2. A one per cent change in the line current very easily may introduce a ten per cent error in the power measurement. The error in the power reading as a function of the deviation of the input impedance of the load attenuator, where it is assumed that the meter attenuator is correct both in attenuation and input impedance, is given by

$$\text{Percentage error}=\left[\frac{k'-k}{1+k}+\frac{\delta R_b}{R_0+R_L}\left(1+\frac{2k'^2}{1-k'}\right)\left(\frac{1}{1+k}\right)\right]\times 100 \tag{7}$$

The derivation of this equation is given in the appendix. δR_b is the deviation of the input impedance from R_b, k is the shunting factor of the meter L pads for the given setting, and k' is the shunting factor of the complete network between battery and bridge. k' should equal k, but the L-pad resistor tolerances and other causes of errors in input resistance, at the same time give rise to tracking errors between the meter and load attenuators, so that the respective k factors of these units are no longer identical.

It may be pointed out that in addition to input resistance variation, another source of line current change is battery drift. The effects of this drift may be

Figure 5. Effect of meter resistance on wattmeter error when attenuator is compensated

A. Maximum R_B, for high bias level bolometer; meter resistance ÷ bridge resistance = 0.5

B. Average R_B, for medium bias level bolometer; meter resistance ÷ bridge resistance = 0.4

C. Minimum R_B, for low bias level bolometer; meter resistance ÷ bridge resistance = 0.35

eliminated, however, by occasionally repeating the bias level adjustment.

The meter network is a cascade of L-pads, the design of which is straightforward.[3] It is seen from Figure 3 that the bridge attenuating network, however, cannot be looked upon simply as a cascade of L-pads because of the presence of the resistance of the metering circuit. If the total impedance of the meter is as small as ten per cent of the load impedance it must be considered as part of the bridge attenuating network. Under this circumstance it is impossible to obtain a constant impedance input for all settings of the attenuator. If the ratio of meter to bridge resistance is sufficiently low, it is possible to compensate the circuit so as to keep the input impedance constant within a small tolerance. This may be seen from the following. The input impedance to the uncompensated network, when all pads are out but the one covering the range from 0–2.7 decibels, is greater than R_b. If the 0–0.3-decibel pad is cascaded with the 0–2.7-decibel pad the resulting impedance is even larger. In the compensating process, the 0–2.7-decibel pad is designed so that when operating as the only attenuator in the circuit the input impedance is less than R_b, and when cascaded with a similarly compensated 0–0.3-decibel attenuator the resulting input impedance is slightly greater than R_b. The maximum deviation is thus reduced. It is unnecessary to compensate the 0–0.04-decibel and 0.025–0.035-decibel attenuator since the value of resistance in their shunt branches is very much greater than the meter resistance. A graphical plot of wattmeter error, as a function of attenuation and the ratio of metering circuit resistance to bridge resistance, comparing the compensated and uncompensated designs, is presented in Figure 4 and Figure 5. The error is calculated from equation (1)–(7). δR_b, the deviation of the input resistance from R_b, is due to the presence of the metering resistance R_m (Figure 3), and involves the analysis of the complete attenuating network. The resistance of the meter circuit depends upon the setting of R_B, the bolometer calibration control. R_m is thus a function of the bias level ($I_0/2$), so that the error is a function of the bias level as well. It is seen that in general the error of the compensated design is considerably less than 1.0 per cent, although at a few isolated points, representing extreme operating conditions, it may rise to 2.0 per cent.

Broad-band Bridge Operation

Microwave attenuators[4] have been designed to be used with the low power and high power bolometers so that power measurement may cover the entire range from 0–5 watts over a broad band of frequencies. The use of these attenuators introduces certain obstacles in direct power measurement. Primarily, the attenuation is not exactly constant over the band. Secondly, the tolerances in the manufacture of the attenuators do not permit of integral power ratios even at midband. Rather than complicate the use of the wattmeter with unnecessary calculations on the part of an operator, a circuit has been devised which enables one to measure the microwave line power as a simple multiple of the wattmeter reading. A variable control is placed across the input to the attenuation network at the points (a-a') Figure 2. When the bridge is initially balanced, the line current differs from the bridge current by the amount shunted off by this control. Since the meter is calibrated at I_0^2 (where I_0 is the battery current), there is an error introduced into the calibration. This error is of the correct magnitude to account for the tolerance of the attenuator.

If the nominal attenuation of the attenuator is α_N decibels, and the calibrated value (a figure usually supplied by the microwave attenuator manufacturer) is α_C decibels, the attenuator tolerance compensator is designed to operate correctly when the value

$$F=\frac{\text{antilog } \alpha_C/10}{\text{antilog } \alpha_N/10} \tag{8}$$

is set on the control. This may be used conveniently to compensate for the attenuation swing of a radio-frequency attenuator if the calibration curve of the latter is known.

Meter Sensitivity

The deflection sensitivity needed for the galvanometer, used as a null indicator, is a function of the bolometer sensitivity, and the minimum change in power the bridge is required to detect. The expression for the unbalance current in a Wheatstone bridge which is almost balanced[5] is

$$i=\frac{(\Delta R_b)I_0}{4(R_b+R_{gal})}$$

where ΔR_b is the deviation of the resistance of the bolometer from its value at bridge balance. For a 200-ohm bolometer with 6,000 ohms per watt sensitivity, and a bias current of 4 milliamperes, a 50-ohm galvanometer requires a sensitivity of 0.5 microamperes per division to detect an unbalance of 2 microwatts. If further wattmeter sensitivity is required a more sensitive galvanometer may be employed. If the above galvanometer is used with a high power bolometer of 60 ohms per watt sensitivity and a bias current of 40 milliamperes, an unbalance of 2 milliwatts may be detected.

Appendix

From Figure 2, the zero adjust line current is

$$I_0=\frac{V}{R_0+R_b} \tag{9}$$

at radio-frequency balance the input impedance of the four terminal network is $R_b+\delta R_b$. $|\delta R_b| << R_b$. The line current is now

$$I_0'=\frac{V}{R_0+R_b+\delta R_b}\simeq\frac{V}{R_0+R_b}\left(1-\frac{\delta R_b}{R_0+R_b}\right)$$

$$I_0'\simeq I_0\left(1-\frac{\delta R_b}{R_0+R_b}\right) \tag{10}$$

The bridge current at the rebalance is

$$I_1=k'I_0'\simeq k'I_0\left(1-\frac{\delta R_b}{R_0+R_b}\right) \tag{11}$$

The current in the shunt branch of the attenuator is

$$I_3=I_0'-I_1$$

$$=I_0(1-k')\left(1-\frac{\delta R_b}{R_0+R_b}\right) \tag{12}$$

The meter attenuator has a shunting factor of k, so that the power indicated by the meter (P_{rfM}) is

$$P_{rfM} = \frac{R_b I_0}{4}(1+k)I_3$$

$$= \frac{R_b I_0^2}{4}(1+k)(1-k')\left(1-\frac{\delta R_b}{R_0+R_b}\right) \tag{13}$$

The true radio-frequency power is the d-c power flowing into the bolometer at zero adjust minus the d-c power at the radio-frequency balance.

$$P_{rfT} = \frac{R_b}{4}(I_0^2 - I_1^2)$$

$$= \frac{R_b}{4} I_0^2 \left[1 - k'^2\left(1-\frac{\delta R_b}{R_0+R_b}\right)^2\right]$$

$$P_{rfT} \simeq \frac{R_b I_0^2}{4}\left[(1-k'^2) + \frac{2\delta R_b k'^2}{R_0+R_b}\right] \tag{14}$$

$$\text{Percentage error} = \frac{P_{rfT} - P_{rfM}}{P_{rfT}} \times 100$$

$$= \frac{P_{rf} - P_{rfM}}{P_{rfM}} \times 100$$

for small errors.

$$\frac{\text{Percentage error}}{100} = \frac{(1-k')^2 + \frac{2\delta R_b}{R_0+R_b}k'^2}{(1-k')(1+k)\left(1-\frac{\delta R_b}{R_0+R_b}\right)} - 1$$

and since $\delta R_b \ll\ll R_T$, and $1+k \cong 1+k'$

$$\frac{\text{Percentage error}}{100} = \frac{k'-k}{1+k} + \frac{\delta R_b}{R_0+R_b}\left[1+\frac{2k'^2}{1-k'}\right]\left[\frac{1}{1+k}\right] \tag{15}$$

When $1-k'$ is small, a further approximation may be made:

$$\frac{\text{Percentage error}}{100} = \frac{\delta R_b}{R_0+R_b} \cdot \frac{2k'^2}{(1-k')(1+k)}$$

$$= \frac{\delta R_b}{R_0+R_b}\,\frac{k'^2}{(1-k')} \tag{16}$$

NONMEMBER AIEE

W. A. LYNCH
NONMEMBER AIEE

Synopsis: Solutions of some of the problems arising in the development of a broad-band signal generator are presented. Three internal cavity, reflex klystrons are used to cover the frequency range. Attenuator and wavemeter designs in coaxial radio-frequency cable are discussed as well as attenuator calibration and accuracy of output power as read from a panel control. The method of pulsing the klystrons is described with emphasis on the problems involved in obtaining very short rise and decay times.

CALIBRATED sources of signal power are required whenever any particular region of the spectrum is being developed. The greater the frequency range covered by any signal generator, the more useful will the unit be as a piece of laboratory equipment. As in all completely new developments, some compromise between wide frequency coverage and proportionally increased bulk and complexity must be established. The present character of developmental work in the microwave region of the spectrum made it desirable to engineer a signal generator covering the frequency range from about 4,000 to 10,000 megacycles per second.

The design and construction of such a signal generator is described in this paper, and the solutions to some of the major problems involved in obtaining the desired performance are discussed.

The complete signal generator is shown in Figure 1. The unit is self-contained with all controls calibrated to an accuracy consistent with present-day requirements. It contains a built-in frequency meter, a meter for constant monitoring of the continuous wave output power, a precision attenuator, a pulse generator, and voltage stabilized power supplies. The d-c power supplies which provide the various voltages are housed in the lower two racks. The pulse generator and delay circuits are contained in the third rack, and the uppermost assembly, a radio-frequency shielded chamber, contains all the microwave components as well as the pulse keyer.

The complete spectrum from 4,200 to 10,300 megacycles per second is covered by three velocity modulation tubes of the reflex type whose outputs are fed through a coaxial line switch to a matching transformer. The switch provides the independent selection of the output from one of the three oscillators, and simultaneously completes the switching by applying the d-c voltages to the desired tube.

A block diagram of the radio-frequency circuit is shown in Figure 2. The capacitative probe in the coaxial line between the matching transformer and attenuator supplies a small fraction of the total power to the frequency meter. The attenuator is of the waveguide-below-cutoff type with matched resistive loops of novel design. Radio-frequency energy flowing into the attenuator is monitored by the launching element which constitutes, in addition, one arm of an a-c bridge. Associated with the bridge is a stable amplifier whose detected output may be observed on a panel meter.

Provisions are made for both continuous wave and pulse operation; and, in the latter case, wide ranges of pulse duration, rate, and delay with respect to a synchronizing trigger are obtainable.

Microwave Circuitry and Components

A survey of existing oscillator tubes operating between 4,200 and 10,300 megacycles per second capable of supplying approximately 100 milliwatts of energy to the attenuator showed that the *2K43*, *2K44*, and *2K39* klystrons could collectively cover the required frequency range. It would have been more desirable to use a single tube requiring less voltage and input power, but no such tube was available. The oscillator tubes selected are normally supplied with narrow frequency range tuners. To facilitate ease of operation, each oscillator tube was provided with a broad-band mechanical tuner that permitted satisfactory tuning over the entire range of each tube. Tests showed that if the cavity resonator grids were kept parallel as the tubes were tuned

Figure 2. Block diagram of the radio frequency section

Figure 3. Attenuator and power meter circuit

over their respective frequency ranges, sufficient power output would be available.

Since three oscillator tubes were utilized to cover the frequency range 4,200 to 10,300 megacycles per second, some switching arrangement was necessary. A single-pole six-throw radio-frequency coaxial line switch was modified to apply the minus 1,250 volt beam voltage to the desired tube as well as completing the radio-frequency connection to the coaxial line system. The reflectors and control grids are left in the circuit at all times.

The power output of a klystron is dependent upon many factors, one of which is the complex impedance of the output circuit. A matching transformer consisting of a single variable length stub and coaxial line stretcher was used to vary this impedance. By using dielectric rods to change the electrical lengths in the matching transformer, it was possible to eliminate all sliding contacts.

The radio-frequency energy is fed into the attenuator which is of the waveguide-below-cutoff type supporting the TE_{11} as the principal mode. Small metal-coated glass tubes having a d-c resistance of approximately 50 ohms are used as power launching and pickup elements. Because of the resistive nature of the metallic films on these elements, and because of their small size, broad-band impedance matching techniques could be utilized. The resistance of these films are a function of the radio-frequency input power, and by making the launching element constitute one arm of an a-c bridge circuit, a broad-band matched power monitor was obtained. This power monitor or bolometer provides the sole means of normalizing the power output calibration.

Figure 3 illustrates the radio-frequency power bridge, amplifier and diode rectifier. Bolometer 2, the temperature compensating element, is identical to the launching bolometer element and is soldered to a large mass of metal to reduce transient temperature fluctuations. Because of the possibility that the klystrons may generate average power up to 0.75 watt at certain frequencies, the platinum-film bolometer elements were designed to withstand one watt average power. Figure 4 shows the power resistance characteristics of a typical element. Changes in the resistance of the bolometer element due to changes in the radio-frequency power input to the attenuator produce an unbalance of the bridge which is amplified and detected. The output of the detector is indicated on a panel meter.

The optimized design of the fixed compensating elements for minimum variation of the impedance of the pickup and launching loops is shown in Figure 5. The voltage standing wave ratio (VSWR) of the output circuit of the generator was measured. The output circuit included a *UG-21B/U* connector and $8^1/_2$ feet of *RG-9/U* cable. The VSWR was found to fluctuate with small changes in frequency as reflections from the load and connector alternately add and cancel. The peak values of these fluctuations are plotted in Figure 6 and show that at 5,350 megacycles per second the combined VSWR reached a maximum of 2.2. Figure 7 shows the average VSWR of the over-all output circuit of the generator plotted against frequency. The VSWR of an average type *B* connector, and the VSWR of the pickup loop which had been computed from the data are plotted on the same graph.

Tests were made to determine the effect of the rapid fluctuation in output impedance with frequency on the output power to a matched load. The output impedance in the frequency band from 5.82 to 6.31 kilomegacycles per second varied through eleven complete cycles (owing to the $8^1/_2$ feet of cable) with eleven maxima averaging approximately 1.56 to 1.60 in VSWR with an average minimum VSWR of approximately 1.10.

A bolometer in a matched mount having a 1.07 VSWR over this band was then used as an output power indicator. The power input to the attenuator was held constant while the frequency was varied over the specified band. The measured output power gradually increased by about 0.6 decibel as the frequency increased. This change compares very favorably with the change in insertion loss of the attenuator over this band.

Since it was at first expected that the power output would vary cyclicly with the output impedance, the theoretical aspects of the problem were examined using the diagram shown in Figure 8. Y_c represents the mismatch admittance of the output connector and Y_o the matched load admittance. This output circuit is

Figure 6. Bands of rapidly fluctuating voltage standing wave ratio in output circuit

Figure 7. Individual voltage standing wave ratio curves of components in output circuit

separated from the pickup loop, Z_g and E_g, by a long length of cable, L. The fluctuating impedance previously mentioned was measured looking into the line at point a, taken to the right of the connector. If Thevenin's theorem is applied at plane a, it must be borne in mind that, because of the presence of Y_c between the pickup loop and point a, both E_{oc} and Z_{in} for the Thevenin circuit will change with frequency. A fixed point at b would be more desirable, since E_{oc} would then remain constant even though Z_{in} would change with frequency, because of the changing electrical length between the pickup loop and point b. An even more desirable condition would be to shift the point b with frequency to keep the electrical length and hence Z_{in} and E_{oc}, constant. This has been done for the representation in Figure 9.

The data given in Figure 9 represent the worst possible combinations of impedance that have been experienced. Z_{in} is the impedance of the pickup loop as seen from point b, which was selected so that Z_{in} was real and maximum. Z_L is the combination of Y_c and Y_o as seen from point b at two discrete frequencies, when Z_L is real and minimum and when Z_L is real and maximum. Point b was shifted as the frequency changed so that Z_{in} (and E_{oc}) remained constant. Since the lengths involved are electrically long, the 180 degree phase shift in Z_L can take place at two frequencies very close together; therefore Z_g and Y_c can be considered to remain essentially constant. P_1 and P_2 are the values of power delivered to the load under the two phase conditions. A is the ratio of these two power levels expressed in decibels.

Over the frequency range for which tests of power variation with frequency were actually made, the equivalent circuit of Figure 10 applies. Hence, over this range, the error in power output to a matched load would be small, approximately ±3 per cent. This was partially obscured in the experimental test by the changing insertion loss.

After taking precautions in the attenuator design to eliminate or reduce to an absolute minimum the possible errors caused by rotation of the pickup loop, impedance mismatch, and radio-frequency choking at the launcher-element, the following factors remained and had to be calibrated:

1. Changing insertion loss of the attenuator with frequency over the range 4,200 to 10,300 megacycles per second.
2. The presence of higher order modes, other than TE_{11}, in the vicinity of the launching and pickup elements.
3. Change in the rate of attenuation with frequency.

The change in insertion loss was compensated by the use of a multiple index on the attenuator dial. A correction for changes in attenuation slope with position and with frequency was made by calibrating the main dial at mid-band and supplying a correction curve for the other frequencies. Figure 12 shows the nature and amount of this correction.

The maximum error in the output power, calibration from the generator is less than ±2 decibels. A summation of the possible errors is as follows:

	Decibels
1. Internal Bridge, Amplifier and Detector Error—This includes ±10 per cent variation in the line voltage, the changing of the mutual conductance of the amplifier tubes with age or by replacement with new tubes, errors in the bridge components, and faulty zero adjustment	±0.35
2. Impedance Mismatch—A discussion of this error is given in the preceding pages	±0.32
3. Calibration Error—The result of reading errors and equipment inaccuracies was estimated to be not greater than	±0.50
4. Bore Error—Even though great care was taken in the boring and final reaming of the cutoff waveguide section of the attenuator, the following possible error must be included in a tabulation of this nature	±0.15
5. Resetability—The dial setting error was estimated as a result of experience gained in calibrating the set to be approximately 0.8 degrees (human error in setting dial)	±0.11
6. Irregularities in the Output Coaxial Cable—Reflections set up in a cable because of manufacturing imperfections and because of twists and bends. Experimental results have shown this error to be approximately	±0.20
7. Temperature—The cutoff attenuator and power measuring bridge were fully compensated for the ordinary laboratory temperature variations; hence no error is placed on this variable.	
8. Backlash—The measured value for this error was ±0.9 degrees which corresponds to	±0.27
Possible Total Error	±1.90

This error is possible only if all of the

component errors are maxima and of such sign as to add. The probable error is, therefore, considerably less than this value.

Because of the nature of the tubes it was impossible to calibrate the oscillator dials in frequency with the desired degree of accuracy. A search frequency meter was, therefore, coupled to the coaxial line. A capacitative probe was used for coupling the frequency meter to the main radio-frequency line. The position of the probe in the radio-frequency circuit is shown in Figure 2. The frequency meter used is a concentric-line resonator with a variable quarter-wave plunger whose drive shaft is geared to a panel control and calibrated dial. Resonance is indicated by the transmission of energy through the cavity to a rectifying crystal, the output current of which is indicated by a panel meter. The coupling into and out of the cavity is accomplished by means of inductive loops. Figure 2 shows this coupling arrangement and the general form of the frequency meter. The oscillation frequency of the klystron tube in use can be measured to an accuracy within ±0.75 per cent.

All the radio-frequency components as well as the keyer circuit were mounted in a large shielded radio-frequency chamber to minimize stray leakage. All seams and joints of this box, excluding the cover, were riveted and welded. All drive shafts were made of insulating materials and were brought out through waveguide-below-cutoff assemblies. The attenuation of each assembly was greater than 100 decibels. Cooling vents were necessary and consisted of honeycombed cutoff waveguide. All electrical leads entering or leaving the shield were filtered by using polyiron chokes whose attenuation at the lowest frequency employed is approximately 100 decibels. The cover was made from 1/8-inch sheet aluminum and was securely fastened in place. A gasket of monel metal fabric was used to prevent leakage at the cover. To insure optimum results from the gasket, the contacting surfaces were given a coating of colloidal silver paint. The same method was used to seal the attenuator opening. All assemblies mounted on the walls of the shielded chamber were designed with wide flanges for clamping purposes. To insure leak-proof mountings, the joining surfaces were kept clean and were given a coat of colloidal silver paint.

Tests made at 9,000 megacycles per second to determine the effectiveness of the shielding, showed the maximum radio-frequency leakage to be approximately 90 decibels below one milliwatt.

Pulse Modulation

The requirements placed on the characteristics of the radio-frequency pulse were exceedingly rigorous. The rise and delay time of the radio-frequency pulse were held to approximately 0.1 microsecond. The peak radio-frequency power under all conditions of pulse duration and rate is maintained the same as the normalized continuous wave power, by designing the pulse keying modulator so that the reflector voltage during the pulse is

Figure 13. Simplified schematic diagram of pulse generator and keyer

Figure 14. Diagram showing method of pulsing reflector voltage

returned to the same value as that for continuous wave operation at which the initial radio-frequency adjustments were made. The circuit diagram of the complete pulse generator and keyer is shown in Figure 13.

The pulse generator itself consists of two synchronizing amplifiers, a free-running multivibrator determining the pulse repetition frequency, a synchronizing output trigger circuit and cathode follower, a delay one-shot multivibrator and a cathode follower to drive the keying multivibrator. Because all panel controls were calibrated directly to ±10 per cent, interaction between stages in this unit was eliminated through the liberal use of decoupling and voltage stabilizing circuits. The pulse generator has a repetition rate range from 50 to 5,000 pulses per second and a pulse delay range from 1 to 100 microseconds with reference to the output synchronizing trigger. Through the use of switching arrangements, the following modes of pulse operation are available:

1. Normal operation, namely, the repetition rate variable over the entire range from 50 to 5,000 pulses per second and generated internally.
2. Synchronization of the pulse generator with an external trigger either positive or negative.

The reflectors of the three klystrons as well as the plate of the clipper diode, Figure 2, are connected together, and the video pulse is applied at this point. The total parasitic capacitive load on the keyer is about 40 micromicrofarads. Because the rise and decay times are held to a minimum, this capacity makes it necessary to develop the pulse across a very low impedance. The final circuit makes use of an 800-ohm resistor in the plate circuit of the 807 section of the multivibrator, Figure 13.

The method of pulsing the klystrons consists of applying a positive pulse whose base voltage is negative with respect to the reflector voltage, thereby causing the reflector voltage to shift to a value which stops oscillation in the time duration between pulses. This is shown in Figure 14. The degree by which the reflector is driven negative is equal to the peak pulse voltage; hence when the pulse appears across the load resistor, the reflector voltage is restored to the normal continuous wave value. This method of pulsing produces a steep rise and decay time on the radio-frequency pulse which is always equal to or better than the video pulse because of the clipping action of the klystron itself. The final radio-frequency pulse was symmetrical with the rise and decay time approximately equal to 0.1 microsecond. The keying multivibrator also controls the pulse width by placing a variable resistance in the grid return circuit of the 807. The pulse width is variable between 0.5 and 30 microseconds and is directly calibrated within ±10 per cent.

When switching over from continuous wave to pulse operation, it was found that a serious shift in frequency resulted, which caused a marked degrading of the pulse waveform. This frequency shift was found to be the result of a temperature change due to lower power dissipation in the klystron under pulse conditions. The smaller power dissipation in the klystron when pulsed results in a change of the cavity dimensions and the klystron resonator grid separation. By holding the d-c power input to the klystron constant through the adjustment of the control grid voltage on the klystron so as to return the d-c beam current under pulse conditions to the continuous wave value, the defects under pulsing conditions can be eliminated. Tests showed the frequency shift between pulse and continuous wave operation less than 0.09 per cent when the input power was kept constant. Under these conditions the pulse waveform is essentially the same throughout the radio frequency range, and the peak power during pulses is the same as that under continuous wave calibration conditions.

No Discussion

Microwave Frequency Measurements and Standards

BENJAMIN F. HUSTEN
NONMEMBER AIEE

HAROLD LYONS
MEMBER AIEE

IN THIS PAPER a survey is given of the problem of microwave frequency measurement and standardization from the point of view of the method adopted at the National Bureau of Standards. The bureau's microwave frequency standard, methods of measurement, and accuracy of calibrations are discussed. A brief preview of possible future developments in this field is also given to indicate some of the lines of attack being considered for the extension and diversification of microwave frequency measurement methods and the application of these techniques to related problems.

National Bureau of Standards Microwave Frequency Standard

The National Bureau of Standards microwave frequency standard was designed to provide continuous frequency coverage from approximately 300 megacycles per second up to at least 30,000 megacycles per second. There is also provision for the generation of spot frequencies of highest precision at approximately 1 per cent intervals over the same band of frequencies. The completed unit was designed to be comparatively easy to operate and maintain, to be as free as possible of all spurious frequencies, and to provide sufficient power over the entire range so it would be possible to calibrate most microwave frequency meters without resorting to external voltage sources. The establishment of this microwave frequency standard was initiated by a request of the Joint Communications Board of the United States Joint Chiefs of Staff in 1944. The unit was put into operation in June 1945 with the help of the Massachusetts Institute of Technology Radiation Laboratory.

In order to keep the power requirement to as low a value as possible, sensitive spectrum analyzers or superheterodyne receivers with panoramic adapters are used as indicating equipment. The actual power available up to at least 26,000 megacycles per second is more than sufficient to perform most calibrations even though 10 decibel isolating pads are used on each side of the meter being calibrated.

The complete microwave frequency calibration equipment except the 100-kc primary standard is contained in one room which is well shielded and provided with temperature and humidity control equipment.

The standard microwave frequencies are obtained from the National primary standard of frequency at 100 kc through a system of frequency multiplication, frequency conversion, and harmonic selection. The National primary standard consists of nine quartz-crystal oscillators which are compared automatically with each other and with Naval Observatory time. The absolute value of the frequency of any one of these oscillators is known at all times to within one part in 100 million.

In Figure 1 is shown a picture of the complete microwave frequency generator. The center rack contains the multipliers, decade generator, frequency converters, and variable frequency generators necessary to obtain and multiply the desired frequency to 30 megacycles per second. The top units of the rack on the left are, respectively, the high-frequency multiplier stages and high-frequency filters. Immediately below these units is the spectrum analyzer with interchangeable microwave plumbing. This equipment is set up for the calibration of a 9,000-megacycle frequency meter. The equipment in the right-hand rack is used to determine precisely the frequency of the variable low-frequency oscillators when they are being used.

Additional equipment not shown in the picture but used during some calibration includes superheterodyne receivers and panoramic adapters which cover the range from 300 to 3,000 megacycles per second and various voltage generators which cover a considerable part of the spectrum between 300 and 30,000 megacycles per second.

Continuous Coverage System

The block diagram in Figure 2 shows the microwave standard set up for continuous coverage. This 100-kc output from the primary standard, after passing through a distribution amplifier, is multiplied to 7,500 kc. This frequency then is added to the output of one of two precision variable oscillators to give an output which is variable from 9.5 to 10.3 megacycles per second. Although, for simplicity, it is not shown in the block diagram, it is possible to add a fixed frequency to the output of either of these oscillators through the equipment used for spot frequency generation so as to obtain a frequency range from 2.0 to 3.0 megacycles per second, which when added to the 7.5 megacycle frequency results in an output variable from 9.5 to 10.5 megacycles per second. In order to reduce the level of undesired modulation products, particular attention was given to the design and construction of the frequency converter where the output of the variable oscillator is combined with the 7.5-megacycle frequency obtained from the primary standard.

The output of the converter is passed through four consecutive frequency triplers with outputs available in the vicinity

Paper 48-49, recommended by the AIEE instruments and measurements committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26-30, 1948. Manuscript submitted November 12, 1947; made available for printing December 15, 1947.

BENJAMIN F. HUSTEN and HAROLD LYONS are both with the central radio propagation laboratory, National Bureau of Standards, Washington, D. C.

Figure 1. Microwave frequency standard

of 30, 90, 270, and 810 megacycles. Each of these stages has a tuning range of slightly greater than 10 per cent so as to accommodate only the range of variable frequency, making it impossible to tune to any except the proper harmonic. The output from any one of these four tripler stages can be impressed across a nonlinear element such as a crystal rectifier which will generate higher-order harmonics. This part of the equipment will be discussed in a following section. The frequency stability of any one of the harmonics will be directly dependent upon the output of the 10-megacycle frequency converter which, in turn, is about 75 per cent dependent upon the primary standard and only 25 per cent dependent upon the precision oscillators. These oscillators are equipped with micrometer dials which give a change in frequency of about five parts in a million per dial division. The instantaneous frequency of the oscillators can be measured to within one cycle by means of the equipment on the right of the block diagram. This equipment consists of a frequency divider, harmonic generators, a receiver, a comparison oscilloscope, and an audio-frequency interpolation oscillator.

Harmonics controlled directly by the primary standard are produced at intervals of 10 kc in the receiver. The unknown frequency and one of these harmonics beat together to produce a beat note which can be measured to within a cycle by means of the interpolation oscillator and the comparison oscilloscope. The interpolation oscillator can, in turn, be calibrated directly against the primary standard.

When the frequency of the variable oscillator is known to within one cycle, the 10-megacycle output and the resulting microwave harmonic are known to within one part in 10 million.

Spot Frequency System

At times a calibration is not desired at any particular frequency but at several points within a range of frequencies. In order to easily obtain such a series of precisely known frequencies the spot frequency generating equipment is used. Figure 3 shows a block diagram of the microwave standard set up for such use. One very apparent simplification is obvious from a comparison with the general coverage system as shown in Figure 2. No auxiliary frequency measuring equipment is needed since the frequency is at all times dependent directly upon the primary standard. The precision oscillators now are replaced by a system of multipliers and converters, called the decade generator, which provides an output adjustable in 100-kc steps from 2.0 to 3.0 megacycles per second. This is accomplished by adding to a 2.0-megacycle frequency the output of any one of a series of frequency multipliers which provide outputs every 100 kc from 100 to 1,000 kc. This frequency then is added to the 7.5-megacycle output and passed through the frequency multipliers as in the previous case. Any one of the outputs is now adjustable over an approximately 10 per cent range at intervals of 1 per cent. Since these frequencies are derived directly from the primary standard, they are known to within one part in 100 million.

Fine Tuning System

An additional arrangement of the equipment is possible, namely, the fine tuning arrangement. This consists of a precision oscillator variable between 500 and 600 kc which can be mixed with the outputs of the decade frequency generator and multiplier to give continuous coverage from 2.0 to 3.0 megacycles per second. The stability of the output from the 10-megacycle converter stage with this system is 95 per cent dependent upon the primary standard and about 5 per cent dependent upon the oscillator. The advantage of this system over the previous continuous coverage system is that each dial division of the oscillator changes the frequency about one part per million as compared to the change of five parts per million of the other oscillators. The frequency of the oscillator is determined by the interpolation equipment as in the previous case and the accuracy of the final frequency is within one part in 10 million.

Generation of Higher-Order Harmonics

Although the output from the microwave frequency standard is tunable over a relatively narrow frequency range, continuous frequency coverage can be obtained through the overlapping of harmonics. With the 10 per cent band width being used, harmonics of the output above the tenth overlap and provide continuous coverage. The 30-megacycle output provides continuous coverage from 285 megacycles, the 90-megacycle output from 855 megacycles, the 270-megacycle output from 2,565 megacycles, and the 810-megacycle output from 7,695 megacycles. The output of any one stage must be used up to the 30th harmonic before the harmonics of the succeeding stage begin overlapping. The power level of the 30th harmonic of any one of the stages is sufficient for frequency calibration purposes.

In order to generate these high-order harmonics the output from any one of the four frequency multiplier stages is impressed across a crystal diode mounted in a coaxial line or a section of wave guide, whichever the case may be. Figure 4

shows one of these crystals mounted in a section of 1-inch-by-1/2-inch wave guide intended to operate in the range from 8,500 to 10,000 megacycles. A typical crystal is shown in Figure 5 and a schematic of the crystal is shown in Figure 6. The crystal is mounted in the wave guide with appropriate tuners so it not only generates the harmonics, but also serves as an antenna for the efficient radiation of the microwave energy down the guide.

The power which these crystals can handle without overloading or burning out is limited. Some of the crystals designed to operate in the vicinity of 1,000 megacycles can handle several watts of power without being damaged, but most of the higher frequency crystals can handle only a few tenths of a watt.

Measurements made on the strength of the harmonics available from a *1N23* crystal diode indicate that with a power input somewhat less than 0.4 watt from the 810-megacycle stage the power level of the 11th harmonic at 8,910 megacycles is about 80 microwatts. The power available at the 30th harmonic of the same stage from a *1N26* crystal diode at 24,300 megacycles is about 0.05 microwatt. Since the sensitivity of the receiver is about 10^{-4} microwatt, there is sufficient power to perform most calibrations.

When a wave guide is used to propagate these higher-order harmonics, no difficulties are ever encountered with lower harmonics or with the fundamental itself since the wave guide transmission line is an excellent high-pass filter, passing only those frequencies which are above the cut-off frequency. When coaxial line is used for the transmission of the energy, it is sometimes necessary to employ tuned stubs or filters in the line to eliminate the stronger lower-order harmonics.

Receiving Equipment

Since superheterodyne receivers used with panoramic adapters are well known, no discussion will be given of this equipment which is used below 2,700 megacycles. The spectrum analyzer and its use, however, may warrant a slight description. The use of and precautions needed with this receiver will apply in general to the panoramic adapter combination.

The spectrum analyzer is essentially a superheterodyne receiver with a frequency-modulated local oscillator. A block diagram of a typical spectrum analyzer receiver is shown in Figure 7. The local oscillator, a klystron tube, is frequency-modulated by means of a saw-tooth wave. This same saw-tooth wave is impressed upon the horizontal plates of a cathode-ray tube. The video output of the receiver is impressed on the vertical plates of this tube. Whenever the difference between the input frequency and the frequency of the local oscillator is equal to the intermediate frequency of the receiver, a pip will appear on the screen of the cathode-ray tube. The height of this pip will be a function of the input power and the position on the screen will be a function of the input frequency and the center frequency of the local oscillator. There will be two such pips for each frequency although they may not be on the screen simultaneously. These pips correspond to instantaneous local oscillator frequencies above and below the input frequency. When the spectrum analyzer is used to compare two frequencies, it is possible for the two to appear to coincide when they are separated by twice the intermediate frequency. When the two frequencies are in proper coincidence the two pips above the local oscillator frequency will coincide as will the two below the local oscillator. Figure 8 shows a close-up view of the spectrum analyzer with one of the interchangeable wave guide assemblies used to cover the various frequency ranges corresponding to each wave guide size.

Measurement of Microwave Frequencies

In order to expedite the setting of the microwave frequency standard, tables to the frequencies of the various harmonics versus the variable frequency input into the 10-megacycle converter have been

Figure 2. Microwave frequency standard continuous coverage with adjustable oscillators

Figure 3. Microwave frequency standard spot frequency coverage

Figure 4. Crystal diode mounted in wave guide

prepared for every 100-kc step from 2.0 to 3.0 megacycles. The frequency to be measured is tuned in on the spectrum analyzer and an approximate value of the frequency is obtained from a calibrated frequency meter. The frequency standard then is set up for the proper frequency by reference to the tables. A pair of pips should appear on the screen of the receiver and by adjusting the power level of the standard or of the generator being measured they can be made equal in amplitude. At this point a check should be made to insure that the two frequencies are approximately equal and are not separated by twice the intermediate frequency. By bringing the frequencies into coincidence and increasing the dispersion it is possible to observe the beat notes on the screen. These beat notes appear as a filling-in of the response curve on the screen. It is possible with this method to determine the frequency of an oscillator to within one part in one million, which is considerably better than the stability of most microwave oscillators. If greater precision is warranted, it is possible to dispense entirely with the spectrum analyzer method and to measure the audio beat note of the two frequencies by any one of several methods.

Microwave Frequency Meters

Microwave frequency meters in common use are of three types

1. Coaxial line.
2. Cylindrical cavity.
3. Transition, which is a combination of 1 and 2.

Since these meters are resonant cavities the terms frequency meter, resonant cavity, and cavity often are used interchangeably. These meters may be of either the transmission type or the reaction type. The reaction-type meter is coupled into the main transmission line through a T section or through an iris in the side of the wave guide. The coupling is adjusted so the meter will present a high impedance in series with the wave guide when it is tuned to resonance, thereby decreasing the power transfer of the guide. The meter is adjusted to resonance by tuning for minimum output.

The transmission-type meter is inserted directly into the line and the energy must pass through the meter. Resonance in this meter is indicated by maximum power transfer. In Figure 9 are shown some typical microwave resonant-cavity frequency meters.

Accuracy of Calibration

Although the frequency from the microwave frequency standard is known to at least one part in 10 million, it is practically impossible to certify a frequency meter to this accuracy. Many factors enter into the exact determination and certification of the resonance frequency which limit the accuracy of the usual meter to about 1 part in 100 thousand or less.

Mechanical inaccuracies such as dial backlash, loose or faulty mode dampers, creepage of the metals or dielectrics, and lack of ruggedness are obvious limitations to the accuracy but are not the only factors which must be considered. When a precise determination of the resonance frequency is desired, such variables as temperature, humidity, and pressure may have to be considered. In addition to these factors the amount of external reactance which is coupled into the frequency meter will also affect the resonance frequency and must be taken into account or made negligible during the calibration. Finally, the sensitivity of the resonance-indicating device and the finite Q of the meter itself limit the accuracy to which resonance can be determined.

From rigorous field theory it is possible to develop equations which describe the behavior of a resonant cavity in terms of the electric and magnetic fields at chosen planes of reference. It is possible to write these equations in very simple form for the behavior of a cavity in the immediate vicinity of a resonance frequency. The equations given here are for the case of a cavity with electrically identical input and output couplings. The equations in this form are from the unpublished notes of David Kerns of the National Bureau of Standards. Similar expressions in different forms have been derived by other investigators.[1]

$$I_1 = I_2$$

$$V_1 = \frac{2Q_L}{\sqrt{T}}\left(\frac{1}{Q_0} + \frac{2j\,\Delta f}{f_0}\right) I_2 + V_2$$

I_1 and V_1 are, respectively, the linear measures of magnetic and electric fields at the input plane of reference. I_2 and V_2 are similar measures at the output plane. The physical meaning of the equations is given in essence by the fact that $V_1 I_1^*$ is the input power; $V_2 I_2^*$ is the output power from the cavity.

Q_0 is the unloaded Q of the cavity.
Q_L is the loaded Q measured with reflectionless loads at the planes of reference.
T is the ratio of the output power to the incident power at resonance and with reflectionless generator and load.
f_0 is the resonance frequency and
$f = f_0 + \Delta f$
I^* is the complex conjugate of I.

Any number of circuits can be imagined whose terminal voltages and currents are connected by these equations, the simplest being the complex impedance

$$\frac{2Q_L}{\sqrt{T}}\left(\frac{1}{Q_0} + \frac{2j\,\Delta f}{f_0}\right)$$

in series with a generator and a load. This, or any of the other circuit arrangements which can be derived from these equations, can be called the equivalent circuit of the cavity resonator in the immediate vicinity of a resonance frequency.

The resonance frequency of the transmission-type resonant cavity is the frequency at which maximum power transfer occurs. At this frequency the reactive component in the series impedance becomes zero. Δf in the basic equations becomes zero. The accuracy to which the cavity can be set to resonance is a function of the loaded Q of the cavity and the sensitivity of the indicating system. The higher the Q of the cavity and the smaller the percentage change in output power or voltage which can be observed in the indicator, the greater will be the accuracy of setting. The indicator used at the National Bureau of Standards for most frequency-meter calibrations is a spectrum-analyzer receiver. The height of the response on the oscilloscope screen is approximately proportional to the input power.

In the present notation a matched (reflectionless) impedance is represented by the normalized value unity. By solving the basic equations for a load impedance $V_2/I_2 = 1$, and a source impedance also equal to unity, one finds that the ratio of the power delivered to the load at a frequency f to that delivered at the resonance frequency f_0 is

$$\frac{P}{P_0} = \frac{1}{1 + Q_L^2\left(\frac{2\Delta f}{f_0}\right)^2}$$

where

$f = f_0 + \Delta f$

This ratio is also approximately equal to h/h_0, the ratio of the responses on the oscilloscope screen

$$\frac{\Delta f}{f_0} = \pm\frac{1}{2Q_L}\sqrt{\frac{h_0 - h}{h}} = \pm\frac{1}{2Q_L}\sqrt{\frac{\Delta h}{h}}$$

If $\Delta h/h$ is the smallest fractional change which can be detected in the indicator, then $\Delta f/f_0$ is the uncertainty in the resonance setting. With the indicating equipment now being used it is possible to detect changes in h of about 1 per cent.

For the typical case of a 10,000-megacycle transmission-type frequency meter with a loaded Q of approximately 10,000, the resonance frequency can be determined to within ± 0.05 megacycle.

Although this derivation and example is for a transmission-type meter, it has been found that when the same meter is used as a reaction-type instrument, the inaccuracy of setting is but slightly greater than that of the transmission type.

Figure 5. Silicon crystal diode

When greater accuracies are desired, some other method of indicating resonance must be used. It is possible to increase the accuracy by working on the steep sides of the resonance curve rather than at the relatively flat top. One means of accomplishing this is to inject a low frequency into the harmonic generating crystal along with the standard frequency. This low frequency is adjusted so it produces side-band markers on the microwave harmonic at approximately $f_0/2Q_L$ on each side of the carrier. It is possible to suppress the microwave carrier to a considerable extent by adjusting the level of the low-frequency input. If the response of the indicating system is uniform over the band width f_0/Q_L, resonance is indicated when these two markers are of equal amplitude. With this indicating system it is possible to set the frequency meter in the preceding example to within ± 0.02 megacycle at 10,000 megacycles per second.

An instrument capable of great accuracy in the setting of the resonance frequency is the cavity Q meter as developed by the staff of the MIT Radiation Laboratory.[3] By means of a frequency-modulated oscillator the resonance curve of the cavity is displayed on an oscilloscope screen. The same oscillator beating against the microwave harmonic from the frequency standard produces two bright spots on the resonance curve. By adjusting the intermediate-frequency amplifier of the Q meter these spots can be made to appear at the half-power points of the curve.

Cavity resonance is indicated when these spots are symmetrically placed on the curve. It is possible to set the meter to resonance to within a fractional error $\pm 0.01/Q_L$.

Frequency Pulling by External Reactance

During the calibration or use of any frequency meter it is essential for highest accuracy that the meter be isolated from external reactances by means of matched buffers. These buffers, usually resistive pads with an attenuation of about 10 decibels, are placed at both sides of the meter to prevent reactances in the line from "pulling" the resonance frequency of the meter. In calculating the extent of this pulling it is assumed that an impedance with a series reactance component jX (normalized value) appears at the output reference plane. For the moment it is assumed that the generator impedance is unity.

Because of this added reactance the reactive components in the circuit will now total zero at a frequency which is slightly different from the true resonance frequency. Again employing the basic cavity equations, the condition for resonance can be written

$$\frac{j4Q_L}{\sqrt{T}}\frac{\Delta f}{f_0} + jX = 0$$

or

$$\frac{\Delta f}{f_0} = -\frac{\sqrt{T}}{4Q_L}X$$

For applications of this equation to wave guide techniques it is convenient to express $\Delta f/f_0$ in terms of a voltage standing-wave ratio (VSWR), rather than in terms of the normalized reactance. From transmission-line theory it can be shown that the maximum magnitude of normalized reactance for a given VSWR on the line is $(r^2-1)/2r$ where r is the VSWR. Therefore

$$\frac{\Delta f}{f_0} = \pm\frac{\sqrt{T}}{8Q_L}\frac{r^2-1}{r}$$

This frequency shift is the maximum for a given VSWR existing at the output of the meter.

Any reactance at the generator side of the cavity will also cause a frequency pulling. The maximum possible frequency shift will be the sum of the two individual shifts.

Referring to the frequency meter of a previous example, $f_0 = 10{,}000$ megacycles, $Q_L = 10{,}000$, it will be assumed that the insertion loss of this meter is 6 decibels. A VSWR of 2.0 at the output side of the meter can produce a frequency shift of approximately ± 0.1 megacycle. If the meter also sees a similar VSWR at the input the possible frequency shift becomes ± 0.2 megacycle.

When a matched attenuator is placed between the meter and the rest of the circuit, the standing-wave ratio which the meter sees will be considerably reduced. For example, an infinite voltage standing-wave ratio will be reduced to 1.22 through a perfectly matched 10-decibel attenuator. If such attenuators are used with the meter in the previous example, the VSWR will be reduced from 2.0 to 1.07 and the frequency shift will be reduced to ± 0.02 megacycle.

The usual attenuator is not perfectly matched but does introduce standing waves, which may enhance the standing waves from other discontinuities. If the 10-decibel attenuator pads have a VSWR

Figure 6. Schematic diagram of a crystal diode

of 1.10 or less, the maximum frequency shifts which can be expected will be

$$\pm 0.16 \frac{\sqrt{T}}{Q_L} f_0$$

(± 0.08 megacycle for the meter of the previous example).

It is apparent that in order to eliminate the possibility of frequency pulling, the meter should be isolated by resistive pads which are in themselves fairly well matched to the line, not only during the calibration but also during the use of the meter. If no suitable attenuators are available, the line should be adjusted so it appears flat looking either way from the frequency meter.

Effects of Temperature, Humidity, and Pressure

Changes of temperature, humidity, and pressure in general will affect the calibration of the cavity-type frequency meter. The actual percentage change in the resonance frequency for a given change in the foregoing factors will depend upon the type of construction and upon the materials in the meter.

The most obvious source of error lies in the change of cavity dimensions due to thermal expansion of the walls. From the principle of electrodynamic similitude[8] it follows that in the case of a perfectly conducting cavity, regardless of the shape of the cavity or the mode of oscillation, an increase in all the linear dimensions by a factor m will decrease the frequency by a factor $1/m$.

Neglecting second-order effects, this can be expressed for small changes in dimensions as

$$\frac{\Delta f}{f} = -\frac{\Delta L}{L} = -\alpha \Delta T$$

where $\Delta L/L$ is the fractional change in linear dimensions, α is the thermal coefficient of expansion for the wall material, and ΔT is the change in temperature. Since the percentage change in frequency for a given change in temperature is proportional to the thermal coefficient of expansion, a cavity made of invar will be much better than one of brass. The thermal coefficient of annealed invar ranges from 1×10^{-6} to 3×10^{-6} while the coefficient for brass is about 19×10^{-6}. If the temperature of the meter during calibration is constant to within ± 0.1 degree centigrade and can be specified to within the same limits, the variations in resonance frequency due to thermal expansions will be about ± 0.02 megacycle at 10,000 megacycles per second for a brass cavity and ± 0.003 megacycle for an invar one. It is possible to introduce compensating elements which will tend to compensate for changes in cavity dimensions so as to keep the resonance frequency constant over a certain range of temperature.

A change in the dielectric constant of the gas in the cavity also will shift the resonance frequency. Changes of temperature, pressure, and vapor pressure in the ambient atmosphere all may affect the dielectric constant of the gas. The extent of this influence will depend upon the type of construction and upon the gas in the cavity. In a sealed unit the type of gas and the moisture content of the gas are determined at the time of construction and remain constant as long as no moisture is condensed out and as long as no leaks develop.

The gas within an unsealed unit is approximately the same as the ambient atmosphere and can be made, for all practical purposes, identical to this atmosphere through a thorough flushing with the ambient air.

A fractional change $\Delta\epsilon/\epsilon$ in the dielectric constant will produce a fractional change in frequency of approximately $\Delta f/f = -1/2(\Delta\epsilon/\epsilon)$. The dielectric constant of air for normal ranges of temperature and pressure is given to a close approximation by

$$\epsilon = 1 + \frac{208}{T}\left(P + \frac{4800}{T} Pw\right) 10^{-6}$$

where P and Pw are respectively the total pressure and the water vapor pressure in millimeters of mercury and T is the temperature of the air in degrees Kelvin.

If the cavity has been filled and sealed with completely dry air or a dry nonpolar gas, Pw will be zero and there will be no change in dielectric constant with respect to temperature. However, if the cavity had been filled and sealed with air containing some water, the change in dielectric constant would depend upon the amount of water vapor present. For temperatures above the dew point of the atmosphere in the cavity, this change is small. The fractional change in frequency for small changes in temperature is approximately

$$\frac{\Delta f}{f} = 1/2 \frac{Pw}{T^2} \Delta T$$

If the temperature falls below the dew point, moisture will collect on the surfaces in the cavity and the frequency error may become quite large.

Changes in external pressure have no effect on the resonance frequency of a sealed cavity unless the pressure difference becomes large enough to distort the cavity.

Unsealed cavities cannot be calibrated accurately because the temperature and humidity of the air in the cavity cannot be specified with great precision. Not only is the accuracy of the unit limited in use because of temperature and humidity variations, but in addition, the initial calibration against a primary standard is limited in accuracy by the same factors. Changes in atmospheric pressure also affect the resonance frequency of an unsealed cavity. The pressure in the cavity however, is identical to the ambient pressure which can be measured with good precision and corrected for, if necessary.

As an example of the magnitude of these variations it will be assumed that the operating conditions for an unsealed invar cavity are 25 degrees centigrade, 50 per cent relative humidity, and 760 millimeters of mercury. A temperature increase of 1 degree centigrade will cause a fractional change in frequency of -3×10^{-6} through thermal expansion of the wall and $+2\times10^{-7}$ through changes in the dielectric constant of the air. An increase of 2 per cent in the value of the relative humidity will cause a fractional frequency change of -3×10^{-6}. A change of 1 centimeter of mercury in the pressure will introduce a fractional change of -4×10^{-6}.

In order for a precision meter to be

Figure 7. Block diagram of spectrum analyzer

Figure 8 (above). Spectrum analyzer with interchangeable wave-guide assemblies

Figure 9. Microwave frequency meters

relatively free of external effects the design of such a meter suitable for use as a secondary standard should embody the following features:

1. The meter should be rigidly constructed of materials which will not creep or change dimensions.

2. The materials should have a low coefficient of thermal expansion and should exhibit no anomalies in the coefficient of expansion with temperature cycling.

3. Temperature compensation may be employed.

4. The electrical design should be consistent with high Q requirements and there should be no interfering modes of oscillation. Mode suppressors should be electrically and mechanically stable.

5. All moisture should be removed from the cavity including that absorbed in the walls and in the damping material. The cavity should be filled with a completely dry inert gas and sealed.

Conclusion

In conclusion, it may be of interest to consider some possible future developments and applications in the field of microwave frequency measurements. Some of the developments to be mentioned are already well under way.

There is an urgent need for improved cavities having very great stability. One method of attack on this problem is the consideration of cavities made of quartz in order to reduce temperature variations. The quartz is silver plated in order to form a metallic wall for the cavity. A solid quartz cavity, of course, will be impervious to moisture.

Cavities, particularly highly stable ones, can be used to stabilize klystron oscillators by means of a microwave discriminator circuit.[4] This results in a standard-frequency generator having considerable power output. In this way, the cavity is used as an active rather than a passive frequency standard. Such an oscillator can be quite useful in frequency measurements as an interpolation oscillator just as such a unit is used in low-frequency technique. It also has been proposed by the MIT Radiation Laboratory to use such cavity-stabilized oscillators for microwave communication systems in which an enormous number of radio channels are made available in a given range of the frequency spectrum because of the great stability achieved. It would then seem to be possible to use a cavity-stabilized transmitter in much the same way crystal-controlled transmitters are used at lower frequency, except that turning over all the channels is achieved with only one cavity.

By means of resonant cavity techniques and accurate frequency measurement methods, a general method for the measurement of complex dielectric constants is obtained.[5] When a dielectric substance is inserted in a resonant cavity, measurement of the change in resonance frequency and the change in Q or band width of the cavity gives one a measurement of the dielectric constant and the power factor of the substance introduced into cavity. This method gives an extremely interesting way of measuring relative humidity of atmospheric air and of the index of refraction of atmospheric air as needed for the study of microwave propagation. One method of making a microwave refractometer using these principles is to use two cavity-stabilized oscillators which are tuned to zero beat. Introduction of atmospheric air in one of the cavities then changes the frequency of the oscillator and a measurement of the beat note gives the index of refraction directly.

Another application of resonant-cavity frequency measurements is to a new and precise determination of the velocity of radio waves, or determination of the universal constant c by measuring the resonance frequency and dimensions of a cavity with extreme precision. This investigation is being carried out at Stanford University under Professor W. W. Hansen. Here even the effect of finite conductivity of the walls of the cavity must be corrected for by adding the skin depth of penetration of the current on the walls of the cavity to the dimensions of the cavity.

It is becoming more and more urgent to extend the range of the Bureau's microwave frequency standard above 30,000 megacycles per second. This problem is being attacked by development of a lighthouse-tube frequency multiplier circuit which will provide, through the preceding multiplier chain, crystal-controlled output in the 2,400-megacycle range. By development of suitable crystal rectifier mounts, harmonic generation at a useful power level should be possible to 75,000 megacycles or higher. It is also possible to use Sperry klystron frequency-multiplier tubes to obtain crystal-controlled power at 10,000 megacycles at a level of approximately one milliwatt. By harmonic generation it then should be possible to obtain useful outputs to 100,000

megacycles and higher. At these extreme high frequencies it probably will be desirable to introduce new frequency measuring instruments along the lines of optical equipment. In this connection, microwave interferometer and echelon gratings have been built and have become practical.

In the higher frequency ranges, many substances have spectroscopic absorption lines.[6] A familiar example is ammonia gas which has a very strong absorption line at about 24,000 megacycles. This line is so broad due to molecular collisions that, at atmospheric pressure, the absorption is quite strong even at 9,000 megacycles. Many other gases have been shown to exhibit such absorption and it is likely that additional gases will be found at still higher frequencies, in what can be called the millimeter wave-length bands. Under the proper conditions of low pressure some spectrum lines are extremely narrow so that it may be possible to use such lines as frequency standards and even to control the frequency of oscillators or to use the lines in conjunction with cavities. The use of spectrum lines as microwave frequency standards is, in many ways, analogous to the use of optical spectrum lines as length standards by relating their wavelength to the standard meter. A standard-frequency generator like the one described in this paper can be used to measure accurately the frequencies of absorption lines. However, a quite compact standard-frequency generator, for providing precision marker frequencies to be used for microwave spectroscopy measurements, can be constructed by means of a quartz crystal oscillator and frequency multipliers driving Sperry klystron multiplier tubes.

At the present time, it is hoped that microwave frequency standards at institutions other than the National Bureau of Standards can be standardized through utilization of the standard frequency emissions from station *WWV*. This is particularly easy if the microwave frequency standard is of a type similar to that used at the National Bureau of Standards, since it will only be necessary to adjust the quartz crystal oscillator or other oscillator, serving as the starting point of the frequency multiplying chain, to the frequency of *WWV* by means of the proper receiver and intercomparison circuits. In the future, if suitable absorption lines can be found for use as frequency standards, it may be possible to calibrate the various types of microwave frequency standards, wherever located, through the use of spectroscopic frequency standards. At the present time frequency measurements and calibrations of frequency meters or voltage sources can be obtained from the National Bureau of Standards as a calibration service similar to the standards services rendered by the Bureau in other fields of measurement.

A Standard of Attenuation for Microwave Measurements

R. E. GRANTHAM
NONMEMBER AIEE

J. J. FREEMAN
NONMEMBER AIEE

IN LINE with the program of the National Bureau of Standards for extending the standards of electrical quantities up through microwaves, the establishment of a standard of attenuation was undertaken. For such a standard to be useful, it must be readily adaptable to the calibration of commercial attenuators over the entire frequency range. Also, for self-consistency, such a standard must be capable of being checked by d-c measurements, thus relating the radio-frequency (r-f) standard to the more accurate primary standards.

A standard of any physical quantity consists not merely in the unique specification of that particular quantity, but equally important, in the specification of the operations, or procedures, through which an unknown quantity is measured in terms of it. The purpose of this paper is to describe such a standard, and the preliminary experiments employed in its evaluation and development.

General Description

Because of the extremely wide frequency range over which attenuators must be calibrated, the construction of a series of standard microwave attenuators to cover the entire spectrum, and the use of the direct substitution method of calibration, is impracticable. A modification of direct substitution, namely, the heterodyne or intermediate-frequency (i-f) substitution method, has been developed in various laboratories,[1,2] and permits the comparison of an unknown attenuator, operating at an arbitrary frequency, with a standard attenuator, operating at a fixed frequency. Thus, one standard attenuator, operating at a convenient frequency, may be used to calibrate attenuators over the entire microwave spectrum.

Essentially, the heterodyne method operates as follows. A r-f generator feeds power through an unknown attenuator into a linear frequency converter, which converts the microwave frequency into the intermediate frequency. The converter feeds through an i-f standard attenuator into an amplifier followed by a detector and meter. The unknown attenuator is then removed, and the standard attenuator adjusted to give the same meter reading. The attenuation of the unknown is then equal to the increase of attenuation of the standard.

This method assumes that the frequency converter is linear, that is, that the i-f power from the converter is proportional to the input microwave power. For small enough input power this is true for a crystal converter, and the operating conditions for a prescribed departure from linearity may be determined experimentally.

The range of attenuation which may be measured by the heterodyne method is less than that measurable by direct substitution, since in the heterodyne method the maximum permissible power input into the converter is limited by the advent of converter nonlinearity. However, a combination of direct substitution, using a previously calibrated r-f attenuator, together with the heterodyne method, extends the heterodyne attenuation range to that of the direct substitution method, although with a decrease in accuracy.

Detailed Description of the Equipment Used to Evaluate the Heterodyne Method at X-Band

The block diagram of the equipment used to evaluate the heterodyne method is shown in Figure 1. The r-f generator is a klystron providing at least 250 milliwatts of r-f power. The d-c power supplies for the klystron and amplifying circuits are battery-stabilized, rather than voltage-regulator-tube stabilized, and stabilized, and special shock mountings are used to prevent noise modulation of the r-f signal by the blower used to cool the klystron. A very high degree of amplitude stability is necessary in all of the components of the system, because the output meter of the system is sensitive to a 0.2 per cent (0.01 decibel) change in power level.

The frequency of the r-f generator is measured by a calibrated wavemeter in the spectrum analyzer. The amplitude of the r-f output of the generator is monitored by a unit as shown in Figure 2. A sensitive d-c galvanometer in the power monitor gives a unit scale deflection for a 0.05 per cent (0.002 db) change in power level. Variable attenuator A, in Figure 1, is used to calibrate the power monitor.

The r-f generator klystron is followed by buffer attenuator B which prevents changes in impedance caused by inserting and removing the unknown attenuator from changing the load impedance presented to the klystron. Thus the power output and frequency of the r-f generator are maintained constant throughout a measurement. A twenty-db attenuator provides an adequate amount of buffing, as evidenced by the fact that the introduction of a 10 to 1 voltage standing-wave ratio at transformer A resulted in no change of generator output, as indicated by the power monitor.

When measuring the insertion loss of

Paper 48-50, recommended by the AIEE instruments and measurements committee and approved by the technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted November 12, 1947; made available for printing December 15, 1947.

R. E. Grantham and J. J. Freeman are both with the National Bureau of Standards, Washington, D. C.

The authors wish to express appreciation for the valuable services of R. H. McCracken who constructed much of the electronic equipment and performed many of the experiments, and A. A. Feldmann who designed the mechanical features of the wave-guide-below-cutoff attenuator.

Figure 1. Block diagram of the intermediate-frequency method of attenuation measurement

Figure 2. Radio-frequency power monitor schematic

an attenuator, it is necessary to insert the attenuator in a transmission line which is matched looking both ways from the point of insertion. To meet this requirement it is necessary to use adjustable transformers *A* and *B* to match attenuators *B* and *C* respectively as accurately as possible to the characteristic impedance of the wave guide.

Buffer attenuator *C* is needed to isolate the local oscillator from the changes in the impedance of its load which would occur when the unknown attenuator is inserted and removed. The conversion efficiency of the crystal changes appreciably with local-oscillator power. Hence, the local-oscillator power output must be maintained as constant as possible. Twenty db is the minimum attenuation used for buffer attenuator *C*.

The repeller voltage of the local-oscillator klystron is swept by a linear sawtooth voltage so that the beat-frequency output of the mixer sweeps over about 0.5 megacycles per second. The i-f amplifier band width is about 50 kilocycles per second, so the i-f response curve is plotted on the oscilloscope as in the usual spectrum analyzer, but with much more than the usual frequency dispersion. The peak voltage of the pulse on the oscilloscope is measured by a differential vacuum-tube voltmeter, which has a sensitivity of one scale division per 0.2 per cent (0.01 db) change in power level. The reason for sweeping the local-oscillator frequency rather than operating it continuous wave (c-w) is that small shifts in the frequency of the r-f generator or the local oscillator may occur up to about 200 kilocycles per second without causing appreciable variations in the output differential voltmeter. If the local oscillator were operated c-w, the beat frequency could not vary more than about plus or minus 3 kilocycles per second for the same variations in output.

Range of Measurement and Errors of Heterodyne Method

The attenuation range measurable by the heterodyne method is determined by the maximum input power consistent with crystal linearity, and by the crystal noise power. The range of crystal linearity was determined by measuring a fixed value of attenuation as a function of crystal input power, using the apparatus indicated in Figure 3. The measured values of attenuation of a 30-db pad as a function of r-f buffing, and hence crystal input power, are depicted in Figure 4. For 100 milliwatts of r-f input power, it appears that 40 db of buffing attenuation (corresponding to a crystal input power of 10 microwatts) suffices for accuracies of plus or minus 0.02 db.

The crystal noise power was measured to be less than one micromicrowatt. Accordingly, the maximum range of attenuation measurement corresponding to an error of 0.05 db due to crystal noise, is 50 db.

In addition to possible crystal nonlinearity, errors in the heterodyne method may occur through r-f or i-f leakage, mismatch on either side of the r-f or i-f attenuators, frequency and amplitude instability and errors in the i-f standard attenuator. Errors of the i-f standard will be discussed in another paragraph, and the question of errors due to mismatch is too lengthy and detailed to consider at this time. If we neglect the last two sources of error, the over-all accuracy of attenuation measurements with the equipment described herein is estimated to be within plus or minus 0.02 db in the 0-10 db range, and plus or minus 0.2 per cent of the attenuation value in db for the 10-50 db range.

Theoretical Factors Affecting the Choice and Design of the Attenuator

To be suitable as a standard, the i-f attenuator must be able to yield known values of attenuation in terms of an accurately measurable parameter, such as length, or it must be capable of calibration in terms of d-c measurements. First designed by Harnett and Case,[3] the cutoff attenuator, Figure 6, which consists of a hollow tube excited at one end below its cutoff frequency, and a coil or condenser which picks up the attenuated field at the other end, fulfills the former requirement. Since the generated field falls off exponentially with distance from the exciting source, and since the attenuation constant may be computed from the dimensions of the tube, the ratio of any two voltages, or

the attenuation introduced by a given length of tube, is reduced to a measurement of length.

Cross-Section of Tube

However, it is well known that the electromagnetic field generated within the tube consists of the superposition of an infinite number of modes, each of which is attenuated along the axis of the tube as $e^{-\alpha_{nm}z}$, where α_{nm} is a function of the geometry of cross section, and the particular mode. The higher the mode, the greater is its attenuation constant α_{nm}, so that only for large enough values of z do the higher modes become negligible. Obviously, then, the accuracy of the attenuator increases as the ratios of the amplitudes of the higher modes to that of the lowest one decrease, and as the ratios of the attenuation constants of the higher modes to that of the lowest one increase. The comparison of these factors for tubes of circular and rectangular cross section is given in Table I.

Circular Cross Section. The fifth column of Table I enumerates the ratio of attenuation constants, α_{nm}, of the first few modes to that of the lowest mode, for circular cross-section.

From Table I, it is apparent that a measure of purity of mode can be achieved by exciting the TE_{11} mode, and by eliminating the TE_{01}, TE_{21}, and TM_{01} modes through symmetry of excitation. Just as a violin string plucked in the center does not vibrate with even harmonic modes similarly, a proper symmetry of the exciting current distribution in a cutoff attenuator will not excite certain classes of modes. In particular, if one considers the cross section divided into four symmetrical quadrants, and if the current distribution in the right-hand quadrants is the negative mirror image of that in the left-hand quadrants, and if the current distribution in the upper quadrants is the positive mirror image of that in the lower quadrants, then only those modes will be excited for which n, (the mode index indicating angular dependence) is odd, eliminating five of the seven undesired modes listed in the column. However, if one uses an unbalanced generator to excite the attenuator coil, the distributed capacitance of the coil makes the achievement of this symmetry difficult.

The obvious type of exciting symmetry associated with a circular tube is, of course, circular symmetry. In particular, circularly-symmetric capacitative disk excitation, described by Harnett and Case[3] and W. O. Smith[4] will excite only transverse magnetic modes, for which $n=0$; of these the mode with the lowest attenuation constant is the TM_{01}. The danger with this type of attenuator is that any asymmetry will produce a TE_{11} mode which has a lower attenuation constant, and hence, for a large enough value of attenuation, can lead to appreciable error.

Rectangular Cross Section. The first four columns of Table I enumerate the ratios of attenuation constants, α_{nm}, of the first few modes to that of the lowest mode, for several ratios of rectangular cross-section dimensions, a and b. It will be noticed that for $a=b/2$, or less, the unwanted modes decay much faster than for circular cross-section. Also, if the exciting-current distribution is chosen so that to each element of current corresponds its negative mirror image with respect to the plane $x=a/2$, and its positive mirror image with respect to the plane $y=b/2$, then it may be shown that only those modes are excited for which m is even and n is odd. Although this type of symmetry is difficult to achieve at lower frequencies, using coil structures, at microwave frequencies this type of symmetry should be easily obtainable using symmetric windows as the exciting structures.

Reaction Effect

The reaction of the receiver circuit on the exciting current becomes the limiting factor affecting the closeness of spacing between exciter and receiver, when precautions have been taken to reduce the unwanted modes, since exponential decay with spacing implies constant current or voltage excitation, for the TE_{11} and TM_{01} modes respectively. As already mentioned by Harnett and Case,[3] the impedance coupled into the exciter circuit by the receiver decreases as $e^{-2\alpha_{nm}z}$ for the TE_{11} mode, and as $e^{-\alpha_{nm}z}$ for the TM_0 mode, where z is the separation between exciter and receiver. Accordingly, a further advantage of the TE_{11} mode over the TM_{01} mode attenuator is the smaller interaction between exciting and receiving circuits for a given attenuation.

Skin Effect

For a perfectly conducting circular tube, of radius a,

$$\alpha_{11}=\frac{1.841}{a}\left[1-\left(\frac{2\pi}{1.841}\frac{a}{\lambda}\right)^2\right]^{1/2} \quad \text{for the } TE_{11} \text{ mode} \quad (1)$$

$$\alpha_{01}=\frac{2.405}{a}\left[1-\left(\frac{2\pi}{2.405}\frac{a}{\lambda}\right)^2\right]^{1/2} \quad \text{for the } TM_{01} \text{ mode} \quad (2)$$

If one takes into account the effect of finite conductivity, σ, following the method of Stratton,[6] one gets easily, for the attenuation constans,

$$\alpha'_{11}=\frac{1.841}{a}\left[1-\frac{\delta}{a}+\left(\frac{2\pi}{1.841}\frac{a}{\lambda}\right)^2\right]^{1/2} \quad \text{for the } TE_{11} \text{ mode} \quad (3)$$

$$\alpha'_{01}=\frac{2.405}{a}\left[1-\left(\frac{2\pi}{2.405}\frac{a}{\lambda}\right)^2\left(1+\frac{\delta}{a}\right)\right]^{1/2} \quad \text{for the } TM_{01} \text{ mode} \quad (4)$$

where $\delta=\left(\frac{2}{\omega\mu\sigma}\right)^{1/2}$ is the skin depth.

For an i-f attenuator, $a/\lambda<<1$, and it is seen that there is no correction for the TM_{01} mode, whereas the effects of finite conductivity are such as to increase the effective radius from a to $a+(\delta/2)$, for the TE_{11} mode.

Experimental Evaluation of Cutoff Attenuator

Mechanical Description

A circular waveguide-below-cutoff attenuator was built for operation at 20 megacycles per second, with the TE_{11} mode having an attenuation rate of 21 db per inch. The distance between coils is adjusted by a mechanical screw drive, and a mechanical counter reads the attenuation directly in units of 0.01 db. Rectangular coils mounted on precision-made bakelite forms are used in an effort to secure symmetry in the generation of the TE_{11} mode, and hence reduce the unwanted modes. The mechanical precision of construction is such that the accuracy of attenuation reading is ± 0.01 db per inch.

Early experiments with the attenuator revealed that it could not be set to a given attenuation value within plus or minus 0.1 db. The fingers on the moving plunger, as shown in Figure 6, were replaced by helical spring fingers, as described by Sydoriak[2] but with no improvement. Finally, the contacts were removed entirely, and the plunger which supported the coil was constructed of bakelite, eliminating the variable attenuation value for a given setting.

Linearity of Attenuator

Direct Measurement of Attenuator Linearity. In order to check the linearity of the attenuator, that is, the deviation of its rate of attenuation from $e^{-\alpha_{11}z}$, the measurement setup illustrated in Figure 5 was used. The exciting coil in Figure 6 was connected to the i-f signal generator, and the receiving coil was matched to 50 ohms by inserting a resistor and capacitor in series with the coil, and tuning for resonance.

Measurements of the attenuation of a particular 5-db step of the Leeds and Northrup carbon attenuator were made for different separations of the coils in the cutoff attenuator, and were found to be constant within experimental error (plus or minus 0.01 db), for coil separations greater than 20 db (about 1 inch). For smaller separations, the measured values of attenuation were variable, depending upon the angle between the axes of the coils. This departure from linearity was caused partly by the change in exciting current due to coupled impedance of the secondary coil, and partly by the presence of higher order modes.

Measurement of Relative Amplitudes of Higher Modes. The first few higher modes, the TM_{01}, TE_{21}, TM_{11}, and TE_{01}, have attenuation rates of 28, 35, 44, and 44 db per inch, respectively, in the experimental cutoff attenuator. For large enough coil separations the preponderant higher mode will be the TM_{01}, since its attenuation rate is not so very different from that of the TE_{11}. For this condition, a method of measuring the relative amplitudes of the TE_{11} and TM_{01} modes by utilizing their different angular dependence was described by Sydoriak,[2] and developed by Griesheimer.[5] This method assumes that

1. Only the TM_{01} and TE_{11} modes are present in sufficient strength to be of importance.
2. Transfer impedance effects are negligible.
3. The tube cross section has no elliptical eccentricity.

It follows from waveguide theory that the voltage induced in the receiving coil from the TE_{11} mode varies as the cosine of the angle, θ, between the axes of the coils, and that induced from the TE_{01} mode is independent of angle. Then, let

$$V_{TE} = A_1 e^{-\alpha_{11} z} \cos \theta \tag{5}$$

$$V_{TM} = A_2 e^{-\alpha_{01} z} \tag{6}$$

represent the voltage induced in the receiving coil by the TE_{11} and TM_{01} modes, respectively, where z represents the distance between the coils.

Figure 5. Intermediate-frequency measurement setup for comparing wave-guide-below-cutoff attenuator with Leeds and Northrup carbon attenuator

Since these voltages are separated in time phase by an angle ζ which is approximately 180 degrees, the resultant voltage amplitude is given by

$$V^2 = V_{TE}^2 + V_{TM}^2 + 2V_{TE}V_{TM} \cos \zeta \tag{7}$$

This may also be written

$$V^2 = (A_1 e^{-\alpha_{11} z})^2 [1 + r^2 e^{-2bz} + 2re^{-bz} \cos \theta' \cos \zeta - \sin^2 \theta] \tag{8}$$

where

$$r = \frac{A_2}{A_1} \tag{9}$$

and

$$b = \alpha_{01} - \alpha_{11} \tag{10}$$

If we keep z constant, and vary θ, V^2 will have a maximum, V^2_{max}, at $\theta = \pm\pi$, and a secondary maximum, V^2_{submax} at $\theta = 0$, and a minimum, V^2_{min}, at $\cos \theta' = -re^{-bz} \cos \zeta$. If we assume the coils are adjusted for maximum power transfer, $\theta = \pi$, then it follows from equation 8 that the attenuation in decibels introduced by displacing the secondary coil from an initial separation, z_0, between coils to a final separation z, is given by

$$A_{db} = 10 \log_{10} \exp(-2\alpha_{11}[z_0 - z]) + 10 \log_{10} \frac{1 + r^2 \exp(-2bz_0) - 2r \exp(-bz_0) \cos \zeta}{1 + r^2 \exp(-2bz) - 2r \exp(-bz) \cos \zeta} \tag{11}$$

From equation 11, it is seen that the presence of the TM_{01} mode introduces a deviation from the exponential law of decay which obtains when only the TE_{11} mode is present. If we define this deviation of the actual attenuation in decibels from the theoretical exponential value as the error, E_{db}, due to the TM_{01} mode, it follows from equation 11 that the maximum error in a measurement of attenuation where the minimum separation between coils is z_0, is

$$E_{db} = 10 \log_{10} [1 + r^2 \exp(-2bz_0) - 2r \exp(-bz_0) \cos \zeta] \tag{12}$$

The value of E_{db} for a given minimum

Figure 4. Measured attenuation of nominal 30-db radio-frequency attenuator as a function of total buffing attenuation using 100 milliwatts of input power

A buffing attenuation of 40-db corresponds to a crystal input power of 10 microwatts

Figure 6. Schematic diagram of wave-guide-below-cutoff attenuator

Figure 7. Graph of $B = 10 \log (V^2/V^2_{max}$ as a function of angular rotation of coils for TE_{11} mode circular attenuator

separation between coils may be determined experimentally by measuring

$$\frac{V^2_{submax}}{V^2_{max}}$$

and

$$\frac{V^2_{min}}{V^2_{max}}$$

at the coil separation z_0.

It is convenient to define the following quantities:

$$B = 10 \log_{10} \frac{V^2}{V^2_{max}} \tag{13}$$

$$B_{submax} = 10 \log \frac{V^2_{submax}}{V^2_{max}} \tag{14}$$

$$B_{min} = 10 \log_{10} \frac{V^2_{min}}{V^2_{max}} \tag{15}$$

$$\frac{V^2_{submax}}{V^2_{max}} = h^2$$

$$\frac{V^2_{min}}{V^2_{max}} = \beta^2 \tag{16}$$

Figure 7 is a typical plot of B as a function of angle between the axes of the coils, and illustrates the power coupled into the receiving coil as a function of angle of rotation, between the coils. If the two values of B_{min} in Figure 7 are not the same, then a third mode must be present. Also if the minimum points are not displaced by equal angles to either side of B_{submax}, a third mode must be present. Using the measured values of B_{submax} and B_{min} as defined herein, the values for r and ζ may be determined from the following equations, as derived by Griesheimer.[6]

$$J = \left[\frac{h^2 - \beta^2}{1 - \beta^2}\right]^{1/2} \tag{17}$$

$$re^{-bz_0} = \frac{1-J}{1+J}\left[1 + \frac{4\beta^2}{1-h^2}\frac{(1+J)}{(1-J)}\right]^{1/2} \tag{18}$$

$$\cos \zeta = -\left[1 + \frac{4\beta^2(1+J)}{1-h^2(1-J)}\right]^{-1/2} \tag{19}$$

$$\cos \theta' = \frac{(1-J)}{(1+J)} \tag{20}$$

Measurements on the experimental TE_{11} mode cutoff attenuator, using rectangular coils, showed that the angular calibration was symmetrical within the accuracy of the measurement, and it was concluded that there was no appreciable coupling due to modes higher than the TM_{01}. The value of B_{submax} was found to be -0.30, and the value of B_{min} to be -60. From equations 16–20 the following values of r, ζ, and θ' were obtained $re^{-bz_0} = 0.017$, $\zeta = 176.5$ degrees, and $\theta' = 89$ degrees.

The maximum error in attenuation, E_{db}, for this separation was therefore, from equation 12, 0.14 db. For a minimum coil separation corresponding to an attenuation of 20 db, the maximum error

Figure 8. Calculated insertion loss of barium titanate disk for TM_{01} mode versus thickness of disk

in attenuation was 0.08 db. The latter error was not detected by measuring the 5-db step of the Leeds and Northrup attenuator because the error was spread over such a wide range of attenuation that the amount included in a 5-db interval was smaller than the experimental error.

Dielectric Filters. The equation for the TM-mode wave impedance, Z_{nm}, of a circular hollow tube of radius a, containing a medium of permeability, μ_1, and dielectric constant of ξ_1, is given by

$$Z_{nm}=\left[\left(1-\frac{f_{nm}^2}{f^2}\right)\left(\frac{\mu_1}{\xi_1}\right)\right]^{1/2} \tag{21}$$

This simplifies, at frequencies far below cutoff, to

$$Z_{nm}=\frac{-U_{nm}j}{2\pi f a \xi_1} \tag{22}$$

For TE waves, the wave impedance simplifies to:

$$Z_{nm}=\frac{a\mu_1 2\pi f j}{v_{nm}} \tag{23}$$

Here, f_{nm} and f are the cutoff and impressed frequencies, $j=\sqrt{-1}$, and U_{nm} and v_{nm} are numerical factors which depend upon the mode. Hence, a material of high dielectric constant will reflect the TM wave and pass unchanged the TE wave. The high dielectric constant material has a wave impedance, for the TM mode, inversely proportional to the dielectric constant so that a large discontinuity between air and the material would exist and cause reflections of the TM mode. The TE mode, on the other hand, would not be reflected because its wave impedance is independent of ξ_1. Similarly, a material of high permeability could be inserted in the guide to reflect the TE wave, but not reflect TM wave. The theoretical insertion loss for the TM_{01} mode of a barium titanate disk with a dielectric constant of 1,150 is plotted in Figure 8, as a function of its thickness.

The measured insertion loss of a barium titanate disk of 0.25 inches in thickness, having a dielectric constant of 1,150, was 40 db for the TM_{01} mode, and 0.05 db for the TE_{11} mode. To insure an intimate contact between the barium titanate and the inside surface of the cutoff attenuator, the rim of the disk was silvered.

The insertion loss of the barium titanate disk for the TM_{01} mode, and of other types of TM_{01} mode filters described in the following paragraph was measured by replacing the exciting coil in the circular attenuator by a capacitative exciting disk, which excited the TM_{01} mode primarily. At a fairly close spacing between the receiving coil and exciting disk, the amplitude of the TE_{01} mode was measured to be less than 1/1,000 that of the TM_{01} mode. Thus there was ample range for measurement of TM_{01} insertion loss for various filters.

S INCHES	TM_{01} MODE DB	TE_{11} MODE DB
$\frac{3}{16}$	25	5
$\frac{1}{4}$	20	5
$\frac{3}{8}$	12	4.8
$\frac{1}{2}$	9	3.6

Figure 9. Insertion loss of various mode filters for TE_{11} and TM_{01} modes in cutoff attenuator

Metal Mode Filters. Various other types of filters illustrated in Figure 9 were tried. The slit filter, Figure 9e, was used by Sydoriak[2] at higher frequencies, but it is not the best type for i-f frequencies, as the data on Figure 9 indicate, because the slit filter reflects a considerable amount of the TE_{11} mode as well as the TM_{01} mode.

Gainsborough[1] developed the wire filter as shown in Figure 9d. It is not as effective as the copper-strip filter shown in Figure 9c. A little less insertion loss for the TE_{11} mode is obtained if the copper strips are bent so as to be approximately perpendicular to the electric lines of the TE_{11} mode as is shown in Figure 9b. Of course the filters in Figure 9b, c, d, and e must be properly oriented or they will reflect the TE_{11} mode as well as the TM_{01} mode.

Using the metal strip filter of Figure 9b an angular calibration of the cutoff attenuator was made. The value of B_{submax} was zero within limits of measurement, and B_{min} was less than -80.

Comparison With Leeds and Northrup Carbon Attenuator. A calibration of the Leeds and Northrup carbon attenuator was made over a 40-db range in attenuation at 20 megacycles per record. The resulting attenuation calibration checked within 0.03 db the calibration made with direct current. A check was then made by operating the cutoff attenuator as a TM_{01} attenuator as described previously for TM_{01} mode-filter insertion loss. The TM_{01} mode calibration was made at only two values of attenuation, 10 db and 20 db, and the values obtained checked the previous calibration within plus or minus 0.01 db.

Conclusion

The heterodyne or i-f substitution method of calibrating microwave attenuators has been investigated, and preliminary equipment has been built to utilize the method. The accuracy obtained is estimated to be within plus or minus 0.02 db in the 0–10 db attenuation range, and plus or minus 0.2 per cent of the attenuation value in db for the 10–50 db range, assuming unity standing-wave ratio presented to both sides of the attenuator under calibration. The basic standard of the heterodyne method is a waveguide-below-cutoff attenuator operated at an intermediate frequency. A preliminary model of an i-f standard cutoff attenuator has been built, tested, and improved until its accuracy is plus or minus 0.01 db per 20 db unit of attenuation.

Speed-Responsive Devices on Diesel-Electric Locomotives

A. V. JOHANSSON
ASSOCIATE AIEE

THIS PAPER describes a control system used on large diesel-electric locomotives to initiate changes in motor connections at certain train speeds. Figure 1 shows a modern locomotive on which this control system is used.

Most large diesel-electric locomotives employed in freight and passenger service on domestic railroads have two motor combinations, each with one or more steps of motor-field shunting, in order to provide full utilization of engine horsepower over a wide range of train speed while meeting the requirement that the electric equipment be as light in weight as possible, consistent with good performance. High schedule speeds require that within the limits of adhesion, available engine horsepower be delivered to the wheels at all times during acceleration. To accomplish this, it is necessary to change to weak field and to new motor connections at the proper times during the cycle of acceleration. This has been done on freight locomotives by manual selection, with the operator reading a speed indicator and changing his connections at certain train speeds. In passenger service, with its higher acceleration rates and greater schedule speeds, and therefore greater dependence on maintenance of full utilization of engine horsepower during acceleration, it has been found desirable to provide automatic selection of motor connections in order to relieve the operator of this responsibility and to maintain more uniform acceleration of the train than would be had by manual selection.

Several means of automatic selection have been used, the simplest using a voltage relay which operates when the generator voltage reaches a certain point. Another method uses a relay which operates on generator voltage and current, and this method is superior to the first in that it will operate at any engine speed rather than at the top speed only. These methods have been used on older locomotives which did not have field shunting in both motor combinations. When one or more steps of field shunting in each of two motor combinations are required, the number of such relays becomes large, the circuits are rather involved, and transients during switching present a difficult problem. This is especially true when automatic backward transition and unshunting are required.

A new means of automatically selecting motor connections in several steps, either forward with increasing speed or back-

Paper 48-52, recommended by the AIEE land transportation committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted October 30, 1947; made available for printing December 2, 1947.

Figure 4. Speed-sensitive relay panel, front view

Figure 5. Speed-sensitive relay panel, rear view

ward as the locomotive decelerates during operation up a heavy grade, has been devised and applied to new diesel-electric passenger locomotives, electric equipment for which is built by the General Electric Company. This method utilizes a group of relays energized through the medium of a tuned circuit by an a-c generator mounted on a locomotive axle. Because of the tuned circuit, the voltage across the relay coil increases very rapidly as the speed at which the relay is to operate is approached, providing an inherently accurate and stable speed setting of the relay and a drop-out speed close to the pick-up value.

The generator used has a 14-pole permanent-magnet rotor, the output being taken from the stator coils, which are 3-phase Y-connected, with the neutral brought out. The generator is bolted to a special cover on the antifriction journal box on the end of one of the locomotive axles, replacing the journal box cover. The rotor is driven by the locomotive axle through a double-end splined drive shaft. This shaft is so designed that it may be disengaged from the axle, pulled through the rotor, and engaged with a motor-driven calibrating mechanism in order that the generator may be conveniently operated for relay calibration without removing it from the locomotive. Figures 2 and 3 show the generator before and after mounting.

The generator energizes the speed relays and, in addition, the locomotive speed indicator. Each speed-relay panel consists of one or more reactors, suitable capacitors, a full-wave rectifier, a small hermetically-sealed sensitive relay, and a multiple-contact control relay. The control relay, energized by 75-volt d-c locomotive control power fed through the contacts of the sensitive relay, controls field shunting contactors or starts the transition sequence leading to a new motor combination, as the case may be. In addition to the three relay panels required for the two connections of field shunting and the transition, a fourth relay panel may be used to provide a warning of impending locomotive overspeed and to shut off power and apply air brakes in the event of actual locomotive overspeed. One of the speed relay panels before assembly in a locomotive is shown in Figures 4 and 5. A schematic connection diagram of the speed relays and generator on a locomotive is shown in Figure 6. As will be noted from the diagram, the speed indicator is connected between one phase and the neutral of the generator and is therefore not materially affected by the loading presented by the speed relays. The speed relays are connected across two phases of the generator, and operate from the algebraic sum of the voltages produced in each of these phases.

Figure 6. Schematic diagram of relay circuits

Figure 7. Curves showing relay coil voltages plotted against frequency of generator output

In Figure 6 the speed-relay circuits are shown from top to bottom in the order in which they operate, with the one operating at the lowest speed shown at the top. As shown in the diagram, the circuits are alike between the generator and full-wave rectifier except for the circuit operating relay *LS1*. Referring to the curve for this circuit, shown in Figure 7, it will be noted that resonance occurs at 31 cycles

per second. Reactor *L-1* in series with the load is used to hold the output voltage down while above the resonant frequency, as the generator voltage is proportional to speed, and the relay coil current would otherwise rise above a safe continuous value. Since the curves for relays *LS1* and *LS2* are similar in shape and close together in frequency, though the circuits differ, it should be pointed out that each circuit is also used on locomotives requiring other settings, and while the ranges of possible settings for each circuit and set of components overlap slightly, the circuit for *LS2* does not cover enough range to meet the requirements for *LS1*.

As shown by the curves, the relays pick up at a rather low voltage compared with the maximum reached, and this assures the relays' holding in when the droop in voltage occurs at speeds above the resonant point. It will be noted that the relays pick up and drop out on a very steep part of the voltage curve, providing an inherently stable setting and a drop out value close to the pickup value. Where required, the drop out value is raised even closer to the pickup value by means of the insertion of resistance in the coil circuit of the sensitive relay by the control relay operated by the speed relay in each case.

The construction of a speed-relay equipment panel is shown in Figures 4 and 5. The control relay has a separate cover to prevent the entrance of dirt and the sensitive relay is enclosed in a hermetically sealed can. Since the remainder of the equipment is static in type, very little maintenance is required.

The first locomotive to be equipped with speed-sensitive relays went into service during the last year and many others are now in use. Results have been very gratifying both as to stability of settings and reliability of operation.

NONMEMBER AIEE

Synopsis: A series of electric locomotives of varying capacities can be constructed from standardized components suitable for switcher, freight and passenger services. Superior operating characteristics are attained while reducing first and operating costs as compared with existing motive power.

ELECTRIFICATION is widely acknowledged to be the best means yet devised for the operation of a railroad. By its use, a standard of operation can be maintained which is unobtainable with other types of power. This superior service generally is accompanied by a reduction in direct operating expense. The predominant factor which has restricted the more widespread use of electrification is the large initial investment required.

An analysis of many electrifications shows that the locomotives themselves constitute 30 to 40 per cent of the total investment. While it is necessary to reduce the cost of all parts of the electrification system, locomotives play such an important role in the over-all operation of a railroad that a complete survey of the modern electric locomotive is well justified at this time from the viewpoint of its over-all operating characteristics as well as first cost.

Locomotive Requirements

A locomotive should meet certain requirements to be a thoroughly satisfactory vehicle for the movement of present-day rail traffic.

High availability must be provided because low operating costs can only be secured by intensive utilization of the motive power. Without high availability low fixed charges and low maintenance are impossible of attainment. The over-all design must provide a locomotive which will have a minimum of road failures and one which can be easily and cheaply maintained. Motive power has been getting more expensive continually, and more and more attention must be given to the problem of keeping it running.

As train speeds are generally being increased it is essential that the locomotive be a good tracking vehicle. Good tracking characteristics and moderate axle loadings considerably reduce track maintenance and also reduce maintenance on equipment carried on the locomotive.

Rigid standardization is one of the best means for minimizing first costs and maintenance. If standardization is to be carried to its ultimate, many parts of locomotives should be duplicated for both freight and passenger service. The difference in speed between the two is decreasing, and in many instances power is operated interchangeably. Consequently the trend is toward less and less distinction in the construction of locomotives for the two types of service.

In recent years a very material change has come about in the conception of the ideal speed—tractive effort characteristics of a locomotive. This has been brought about largely by the success of the Diesel. Sustained horsepower output is still desirable over the whole speed range. But in addition to this, the advantages of large starting tractive effort and high continuous tractive effort are appreciated more and more, and the economies to be derived from their provision are better recognized. This means that in the design of a locomotive it is desirable to carry, if possible, all of the weight on driving axles. As a means to reduce track maintenance it is preferable to have a large number of lightly loaded axles than a small number of heavily loaded axles. The optimum adhesive weight for a locomotive seems to be about 100 pounds for each rail horsepower. Locomotives built with this weight ratio provide easy handling of trains, give maximum tonnage rating over adverse grades, and reduce helper service.

Summarizing, the requirements for a modern locomotive are

1. High availability.
2. Standardization and low first cost.
3. Low operating and maintenance costs.
4. Good tracking qualities.
5. Light axle loads.
6. Sustained output over the entire speed range.
7. Large starting tractive effort with entire locomotive weight on drivers.
8. High continuous tractive effort.
9. An adhesive weight of approximately 100 pounds per continuous rail horsepower.

Existing Motive Power

No locomotive has altogether met these requirements in the past. The reciprocating steam locomotive has probably departed most from them and this is perhaps one of the main reasons why its popularity has suffered. For the most part a small portion of its weight is carried on drivers with ratios of weight on drivers to rail horsepower as low as 45 to 60 pounds except for articulated types. Even this low ratio is often achieved only by using excessive axle loads, the destructive effect of which on the track is further increased by the dynamic augment of the reciprocating parts.

Paper 48-54, recommended by the AIEE land transportation committee and approved by the technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted November 12, 1947; made available for printing December 17, 1947.

Figure 1. Artist's conception of 7,500-horsepower locomotive

Electric locomotives in the past have met a number of these requirements, but have departed from them in a lack of standardization and in the tendency to concentrate great blocks of power on each driving axle, resulting in insufficient weight—horsepower ratios and inherently slippery motive power with little reserve starting capacity.

The Diesel does not fully meet all of them but it probably comes closer than any other kind now in operation. Inherently a diesel locomotive is heavy and long, introducing factors which result in a high first cost and increased operating expense.

From the maintenance standpoint, steam reciprocating locomotives are most costly, reciprocating Diesel engines next, while the electric locomotive, which carries no prime mover, is the most favorable.

As the electric locomotive does not carry its own prime mover or fuel, it inherently has a greater possibility of meeting all requirements of ideal motive power than any of its competitors. In addition, electrification has a very decided advantage in its sources of energy which are coal, efficiently burned in large central stations, or water power. These constitute the nation's largest and most assured sources of low cost energy. Furthermore, when atomic power becomes a practical source of low cost energy it will be produced initially in large central stations, and will be available to the railroads only if they are electrified.

Proposed Electric Locomotives

The ideal electric locomotive should meet the basic requirements which have been set forth. In addition to those listed, it should be capable of being built in one cab for any capacity required. The general arrangement of the locomotive should permit installation of electrical apparatus to operate from either alternating or direct current. Both systems are widely used throughout the world and both provide excellent means of operation. The locomotives proposed here are of the straight a-c or d-c types which are fundamentally suited for the widest range of applications. The motor-generator and split-phase types show to best advantage only on mountain grades, are more expensive than the types selected, and less flexible in their application.

It is proposed to build, from standardized mechanical and electrical components, a series of locomotives of varying capacities to fill every motive power need in the wide range of railroad application. The first component is a simple four-wheel swivel truck designed to carry two axle-hung traction motors which may be of the a-c or d-c type. This truck, with its motors, will constitute the running gear and main propulsion units which normally require the major part of locomotive maintenance. Consequently, by making all motors and trucks identical, the major part of standardization is accomplished insofar as wearing parts are concerned. A small stock of spare parts can then service a variety of locomotives ranging from switchers to large road units.

In current Diesel practice, the largest concentration of power on a single driving axle is 500 engine horsepower or 400 rail horsepower. For the standardized electric locomotive truck, 469 rail horsepower has been chosen for the capacity of each traction motor, a value that can be met with d-c or a-c motors. By utilizing different numbers of these trucks the following series of single cab locomotives is obtained.

Trucks	Rail Horsepower Continuous	Rail Horsepower Maximum
2	1,875	2,500
3	2,813	3,750
4	3,750	5,000
6	5,625	7,500
8	7,500	10,000

In this series of locomotives, each axle will be loaded to only 45,000 pounds so all will have unusually low wheel loadings, resulting in low maintenance of wheels, track, and bridges, and meeting all main line weight restrictions. This range of sizes should cover any applications now existent or which are predictable in the near future. The largest diesel locomotives currently in service deliver approximately 5,000 rail horsepower while the largest steam engines range between 6,000 and 7,000 rail horsepower. In comparing ratings of different locomotives, it should be kept in mind that diesel and steam horsepower capacities are maximum ratings, while the electric locomotives are continuously rated and can be operated in excess of these ratings for short periods.

Mechanical Arrangement

The proposed standard four-wheel truck will be of special, but not radical, design. It will be a "no-lift" lateral motion truck in which the lateral swing of the bolster is restrained by metallic or rubber springs or, by their omission, allowed free lateral motion. Where more than two trucks carry a single cab, the two outer trucks will have their lateral motion restrained to produce lateral characteristics similar to those of conventional swing link trucks except that there will be no change in the height of the truck centerplate above the rail with lateral motion. The trucks between any two outer trucks will be unrestrained laterally. To further minimize truck-to-truck weight transfer with this arrangement because of vertical curvature or irregularities of the track, the truck is provided with unusually flexible springs having static deflections of the order of $5^1/_2$ inches. With these springs maximum truck-to-truck weight transfer will be held under all conditions to less than 5 per cent.

Normal clearance restrictions can be met with any combination involving up to 16 axles under a single cab with this arrangement. As a matter of fact, a 16 axle, 7,500 horsepower locomotive shown in Figure 1, while approximately 117 feet long between coupler faces and having a cab 90 feet long, meets all normal clearance restrictions on any flat or superelevated curve of 300 feet radius or more with lateral displacements no greater at any point than those of a standard 85 foot passenger car.

The cab will be carried directly on the trucks on two, three or four truck locomotives. The construction used is shown

schematically by the exploded view in Figure 2*a*. When six or eight trucks are required, they will be divided into two groups, each assembled under a subframe with the two frames in turn carrying the locomotive cab, as shown in Figure 2*b*. These combinations are suitable for speeds up to 100 miles per hour with excellent tracking characteristics, and may readily be made to track well at still higher speeds by adding simple damping devices to the trucks.

It should be noted that these locomotives, in the larger sizes, are only about 45 per cent of the length of Diesel locomotives of equivalent rail horsepower. This type of mechanical arrangement would not permit Diesel locomotives to be built to these same lengths because of the space required for the Diesel engines and their auxiliaries.

Electric Equipment

The electric apparatus can be highly standardized to cover the five sizes of locomotives ranging from 1,875 to 7,500 horsepower.

When built for operation under an a-c trolley, one design of traction motor can be used for all services; switching, freight or passenger, the proper gear ratio being selected for each service. Three sizes of transformers will cover the entire range of capacities with two transformers being used in each of the two larger sizes. Most control components will be identical, including such items as unit switches, reversers, master controllers and train line jumpers. Different quantities will be required on different sizes. The same traction motor blowers will be used, each blower supplying four motors. Compact force-ventilated resistor units can be added to provide dynamic braking in freight service when it is desired. This space will be used for train heating boilers for passenger service. All cab apparatus will be grouped in subassemblies which can be readily removed for repair.

When built for d-c operation a single design of traction motor with proper gearing will be used for all services. Traction motor blowers will be identical as will the component parts of the control, varying in quantity only for the different sizes. In other words the same degree of standardization can be carried out whether alternating or direct current.

The electric equipment was selected to provide the fundamental propulsion characteristics required for the chosen axle loading. Generally speaking the most severe duty on the electric equipment occurs in freight service. The motor capacity was selected to give a continuous tractive effort equivalent to $16^3/_4$ per cent adhesion with freight gearing. It has been found from experience that freight locomotives with this adhesion rating are normally self protecting and can be universally applied. Sufficient starting tractive effort has been provided to work the motors at a conservative commutating limit at 25 per cent adhesion, with sufficient margin for emergency starting at 35 per cent adhesion. With these margins the motors can be re-geared for switcher or passenger service.

For some passenger applications it may be necessary to provide a truck, identical with the others but without traction motors, to carry the additional weight of the train heating boiler and its supplies.

The continuous rating of 469 horsepower per motor is ideal for the locomotive weights proposed. As one of the inherent characteristics of electric traction motors is their short time overload capacity, all of these locomotives can exert outputs in excess of their continuous rating for short periods. A satisfactory limit to overload capacity is $33^1/_3$ per cent in excess of the nominal continuous rating, and the output of all locomotives will be automatically limited to this value. By so doing, the maintenance of equipment will be kept low and advantages gained in the construction of the power supply system.

Table I. Weights, Dimensions and Ratings Electric Locomotives—1875 to 7500 Horsepower with Identical Motors and Trucks

	1875 Horsepower	2813 Horsepower	3750 Horsepower	5625 Horsepower	7500 Horsepower
Arrangement					
Total weight—lb	180,000	270,000	360,000	540,000	720,000
On drivers—lb	180,000	270,000	360,000	540,000	720,000
Per driving axle—lb	45,000	45,000	45,000	45,000	45,000
Length over couplers	48′	67′	70′ 4″	99′ 10″	117′ 2″
Length cab	44′	64′	87′	88′	90′
Rigid wheel base	8′ 4″	8′ 4″	8′ 4″	8′ 4″	8′ 4″
Wheel diameter—inches	44″	44″	44″	44″	44″
Number of motors	4	6	8	12	16
Ratings—freight gearing					
Tractive effort—25% adhesion	45,000	67,500	90,000	135,000	180,000
Maximum tractive effort—35% adhesion	62,500	93,750	125,000	187,500	250,000
Maximum horsepower	2,500	3,750	5,000	7,500	10,000
Continuous ratings—$32^1/_3$ mph					
Horsepower	1,875	2,813	3,750	5,625	7,500
Tractive effort	21,625	32,437	43,250	64,875	86,500
Maximum continuous tractive effort	30,000	45,000	60,000	90,000	120,000
Maximum speed—mph	65	65	65	65	65

Figure 3. Performance curve of 7,500-horsepower freight locomotive

Weights, Dimensions, and Ratings

Table I shows the principal weights, dimensions and ratings of the proposed line of locomotives ranging from 1,875 to 7,500 horsepower. In this tabulation the ratings are listed for locomotives equipped with gearing suitable for freight service. If gearing for other services at different top speeds were selected, the speeds and tractive efforts would change accordingly.

One particularly interesting feature of this line of locomotives is the constant weight ratio of approximately 100 pounds per continuous rail horsepower maintained throughout the entire line. Another advantage is the ability to operate any or all combinations in multiple so that if in any particular service it is desirable to operate a two-unit locomotive rather than one big unit, this is entirely practical.

Figure 3 shows the performance curve of the 16 axle locomotive, rating 7,500 horsepower continuously. This locomotive, in a single cab, is capable of delivering 120,000-pounds tractive effort continuously, and a maximum rating of 10,000 horsepower at all speeds between 20 and 65 miles per hour. One electric cab provides approximately the continuous tractive effort of the average 4-unit, 6,000 horsepower Diesel, and twice its maximum rail horsepower.

It has been customary throughout the industry to rate locomotives by horsepower but unfortunately all of these horsepower ratings are not comparable. Steam locomotives are normally rated in cylinder horsepower. Diesel locomotives are rated in engine horsepower available for input to the generator for traction. Electric locomotives are rated in continuous horsepower at the rail. To show a comparison between the various types as they are normally rated, Figure 4 shows the speed-tractive effort performance of reciprocating steam, Diesel and electric freight locomotives per 1,000 horsepower of nominal rating.

One other feature of this curve warrants attention. Electric transmissions can be used on Diesel, steam turbine or gas turbine locomotives. Identical electric drives will give exactly the same performance at the rail irrespective of the prime mover used. The tractive effort which can be developed with any electric drive is a function of the number of traction motors used. The limits shown on this curve correspond to the average for Diesels now in service.

Figure 4. Speed-tractive effort characteristics of steam, Diesel and electric locomotives per 1,000 horsepower of nominal rating

The comparative weights, per rail horsepower, of modern locomotives are shown in the following tabulation.

Type	Total Weight Lb Per Continuous Rail Hp	Adhesive Weight Lb Per Continuous Rail Hp
Proposed electrics	100	100
Reciprocating steam		
(Rigid frame)	140 to 160	45 to 60
(Articulated)	150 to 170	75 to 100
Diesel	155 to 240	135 to 185

Costs

This standardized construction of locomotives, besides making available a series which should meet any predictable operating conditions, will be attractive from the standpoint of low first cost when locomotives are manufactured in quantities comparable to the production of other types. The following tabulation shows the comparative quantity prices of this line of electric locomotives, of modern steam reciprocating locomotives, and of Diesel road locomotives. The Diesel locomotive was selected as the standard of comparison since it is currently being purchased in the greatest quantities.

	Relative Selling Price Per Rail Horsepower (Per Cent)
Diesel	100
Steam reciprocating (rigid frame)	50 to 60
Proposed electrics	
1,875 horsepower	68
7,500 horsepower	58

In appraising this tabulation one other factor should be kept in mind. The electric locomotive inherently has the highest availability of any type and for its horsepower rating will do more work. Consequently, fewer electric locomotives are usually required to do a given job which makes the comparison even more favorable for the electrics than that shown in the table.

On the other hand the electric locomotive requires wayside structures and installations which are necessary for its use. When these are included, the first cost of electrification has generally exceeded that of other types of power. This higher investment can be justified, by the locomotive's ability to do more work at lower operating expense.

It is of equal importance to have locomotives with low operating expense. One of the principle means by which this can be accomplished is with motive power suitable for handling heavy tonnage

trains over any profile with the minimum degree of helper service. Among the proposed locomotives a size can be selected which will fit requirements of any railroad for the expeditious handling of any type of traffic. As all of these locomotives carry their entire weight on drivers, the maximum utilization of horsepower is obtained for every condition required.

A second important item in operating expense is that of fuel or power. The electric locomotive itself is a very efficient machine operating at an over-all efficiency of 80 to 85 per cent from trolley to rail. Actually the expense for power is largely contingent on the price at which it is delivered to the trolley system, a subject beyond the scope of this paper.

The importance of low maintenance cannot be overemphasized. The maintenance expense of some modern locomotives equal their original purchase price in five years. Past performance shows that electric locomotives can be maintained for 1/3 to 1/2 of the cost per locomotive mile of Diesel or reciprocating steam locomotives when comparing locomotives of the same rail horsepower. The proposed line of electric locomotives should offer possibilities of further reduction in maintenance because of their design and standardization which permit the adoption of maintenance methods not heretofore commonly used. It should be possible to eliminate periodical major shoppings entirely. For instance, it will be a very short job to drop out one truck and replace it with one which has, together with its motors, been overhauled. It should be possible to do this without interfering with operating schedules. Similarly all major apparatus within the locomotive cab consists of units which can be removed and replaced without taking the locomotive out of service. Maintenance then becomes a steady shop load which can be handled with a maximum of efficiency so that it should seldom be necessary to remove a locomotive from service to keep it in first-class operating condition.

Conclusion

The ideas discussed in this paper constitute a new conception of electric locomotive design. It is the belief of the authors that they offer a definite basis for the construction of lower cost motive power with improved operating characteristics and reduced operating expense.

Discussion
